Bistable The bistable is an electronic switch with an adjustable on/off setpoint. Within the bistable, a signal from the process sensor is compared to a preset, adjustable setpoint. When the process signal equals or exceeds the setpoint value, the bistable's output is turned off (de-energized), and its output voltage goes to zero (the bistable is tripped). This electronic device or switch thus converts the analog (variable) input signal into a digital (on-off) output signal.

Logic The comparison of input signals, such as signals from instrumentation sensors, to determine whether an actuation of a protective device should occur. An example of logic is 2-out-of-4 inputs indicating that a given plant parameter exceeds a setpoint required for actuation; if only one-out-of-four signals exceeds a setpoint, no actuation will occur.

Moderator Temperature Coefficient (MTC) The effect of a change in the moderator temperature (water in case of light water reactors) on the core reactivity. A positive MTC implies an increase in reactivity due to water temperature increase—an unstable and therefore undesirable situation.

Reactivity A term expressing the departure of a reactor system from criticality. A positive reactivity addition indicates a move toward supercriticality (power increase). A negative reactivity addition indicates a move toward subcriticality (power decrease).

Reactor Scram Automatic insertion of all control rods into the reactor core.

Setpoint A predetermined value at which an action is expected to occur.

Solid State An electronic device in which electricity flows through solid semiconductor crystals rather than through vacuum tubes.

Introduction

In many plant transients, the control system acts to return the reactor to its normal operating condition. However, the more severe transients require that the reactor be shut down by the Reactor Protection System (RPS). The RPS is designed to provide a highly reliable means of achieving reactor shutdown in the event of one of these severe transients. This is accomplished by the RPS monitoring certain parameters and either automatically responding or the operators manually shutting down the reactor. These operator

actions may be accomplished in the control room or from a different location within the plant in which a remote shutdown panel is located. Specific plant parameters monitored for Pressurized Water Reactors (PWRs) and Boiling Water Reactors (BWRs) are identified in **Reactor Protection System**. Plant technical specifications are developed for the RPS instrumentation to assure their operability and accuracy by means of various surveillance requirements.

Throughout this article, the words trip and scram are used to describe the process of automatically shutting down the reactor in off-normal or accident conditions. “Trip” is typically used for PWR plant, while “Scram” is typically used for BWRs.

This article first describes the regulatory requirements for reactor protection, including changes required to address concerns related to events with failures to trip or scram the reactor. Next, representative descriptions of the mechanics of operation of the control rod system in three PWR vendor designs and a General Electric BWR design are provided. This is followed by a discussion of scram failures and anticipated transient without scram (ATWS) events. In response to failures of reactor scram systems at operating plants, additional regulatory requirements were mandated by the US Nuclear Regulatory Commission (NRC) to further assure that the reactor could be shutdown safely. Finally, RPS designs for typical PWR and BWRs, including the logic and instrumentation associated with reactor protection, are described.

Regulatory requirements

As discussed in [Rempe \(2021a\)](#), the predecessor of the NRC, the Atomic Energy Commission, issued a set of General Design Criteria (GDC) for light water-cooled nuclear power plants in what is now found in Appendix A of 10 CFR50 ([NRC, 2020](#)). The GDC establish the necessary design, fabrication, construction, testing, and performance requirements for structures, systems, and components (SSCs) important to safety. That is, those SSCs that provide reasonable assurance that the facility can be operated without undue risk to the health and safety of the public. GDC 20 through 29 are particularly relevant to reactivity control which is undoubtedly the highest priority to assure safe operation of nuclear power plants. These criteria include requirements for:

- Automatic actuation of appropriate systems, including reactivity control systems,
- High reliability and testability so that no single failure results in the loss of system function,
- Effects from natural events, plant operation and accidents to not cause a loss of protection system function,
- Any failure of a protection system to place the plant in a safe state,
- Control systems and protection systems to be separated to the extent possible,
- Protection systems to accommodate a single failure of the reactivity control system,
- Provision for two independent means with different design principles for reactivity protection systems,
- Safe shutdown during accidents by a combination of reactivity control systems and poison injection,
- Safe fuel limits to be maintained by considering the potential amount and rate of reactivity insertion during an accident, and
- A high probability of success of protection systems and reactivity control systems to accomplish their function for anticipated operational occurrences.

In addition, reactivity control systems are subject to regulatory requirements imposed by the NRC in response to events occurring at operating plants (see **Anticipated Transient Without Scram (ATWS)**).

Mechanics of reactor scram system operation

PWR

In PWRs, the control rods are inserted and withdrawn from the top of the reactor vessel (RV) ([Brown, 2021](#)). The control rods are separated into two functional categories: shutdown rods and control rods. Each category consists of several individual rods arranged in banks which are moved together. The shutdown banks are always in the fully withdrawn position during power operations and are moved into this position as the reactor approaches criticality. These shutdown banks provide a large negative reactivity insertion upon reactor trip to ensure the reactor achieves and maintains subcriticality. During plant operation, the position of the control rod banks is changed using the rod control system. A control rod drive (CRD) mechanism is used to withdraw or insert the control rods.

Westinghouse PWRs: The control rod drive mechanism consists of latching assemblies (grippers), the rod drive shaft assembly, and the magnetic coil stack. Every single rod has its own drive mechanism. The primary CRD mechanism is an electromagnetic jack. Movable and stationary gripper latches engage each rod drive shaft when its respective coils are energized. The movable grippers are used to raise or lower the CRD shaft when the lift coil is energized or de-energized. The stationary grippers are used to hold the drive shaft in position when rod motion is not required. A reactor trip is achieved by simply removing the electrical power from the coils, which allows springs to disengage the grippers from the rod drive shafts, and the rods fall by gravity into the core ([NRC, 2009a](#)).

Babcock & Wilcox (B&W) PWRs: The primary components of the CRD mechanism consist of an electrically driven, roller nut assembly, a stator, and a leadscrew that converts the rotary motion of the roller nut assembly to the linear travel of the leadscrew and control rod assembly. As the power to the stator coils is sequenced, the roller nut assembly rotates to a new position. The drive is designed to trip whenever stator power is interrupted. The power loss causes the rotor assembly segment arms to pivot, disengaging

the roller nut assembly from the leadscrew and allowing the leadscrew and control rod assembly to fall into the reactor core (NRC, 2011b).

Combustion Engineering (CE) PWRs: The control element drive mechanism consists of a series of gripper latches that fit into grooves in the control element assembly drive shaft. The grippers are magnetically operated, and they position the control element assembly during withdrawal and insertion. Electromagnetic coils, located outside the pressure housing containing the control element assembly, are used to hold and move the control element assembly. The electromagnetic coils become inactive when electrical power is interrupted. The power loss causes the spring-loaded grippers to disengage from the grooves and the control rod assembly to fall into the reactor core (NRC, 2008a,b).

BWR

For a BWR, the control rods are inserted and withdrawn from the bottom of the reactor pressure vessel (RPV) (Harmon, 2021). During plant operation, the position of the control rods is changed using the reactor manual control system. This system opens and closes valves in the CRD system, which provides pressurized water to the Hydraulic Control Units (HCU) on each control rod. The HCU opens and closes directional control valves that control rod movement.

Each of the individual control rods is equipped with two scram solenoid valves. Fig. 1 provides a schematic of the operation of the BWR RPS. When no full scram condition is present, the scram air header is pressurized from the plant instrument air system to maintain the spring loaded HCU scram inlet and outlet valves closed and the spring loaded scram discharge volume (SDV) vent and drain valves open.

When a reactor scram is initiated by the RPS, the scram pilot air header is isolated and depressurized. This allows spring pressure to open the inlet and outlet scram valves on each HCU and close the (SDV) vent and drain valves. Pressure from the reactor vessel and from the scram accumulator is applied to the area below the CRD while the water above the control rod is allowed to flow to the SDVs. The large differential pressure applied to the control rod drive rapidly inserts the control rod upward into the core.

In addition to the scram pilot solenoid valves, there are two backup scram solenoid valves. The backup scram valves control the air supply to the entire scram pilot air header. When energized the valves reposition, isolating and venting the header. Venting of the scram air header would open any individual scram pilot valve that otherwise fails to open. This provides a redundant means of venting the scram air header and causing rod insertion.

Fig. 1 Simplified BWR reactor protection system. Taken from Fig. 7.3-5 of NRC (2011a) General Electric Systems Technology Manual. Chapter 7.3: Reactor protection system. US NRC Human Resources Training Development (HRTD). Available from <https://www.nrc.gov/docs/ML1125/ML11258A345.pdf>

There are also two SDV pilot solenoid valves that function in much the same way as the HCU scram pilot solenoid valves to close the SDV vent and drain valves on a full scram signal. Upon a full scram condition, they are de-energized to vent the air holding the SDV vent and drain valves open.

Anticipated Transient Without Scram (ATWS)

An Anticipated Transient Without Scram or ATWS event is important to safety because the failure to trip can result in damage to the reactor core due to overheating when the coolant is unable to provide sufficient heat removal. Another concern is the potential for failure of the RPV, and in BWRs, the containment, because of the excessive pressure increase associated with core overheating.

Prior events

ATWS events occurred at Salem Unit 1 in 1982 (two nearly identical events that occurred 3 days apart) (NRC, 1983; Rempe, 2021b). Previously, a failure of a manual scram occurred at Browns Ferry Unit 3 in 1980 (INPO, 1980; NRC, 1980). In 1988 (NRC, 1988), a thermal hydraulic instability event occurred at LaSalle Unit 2. In each of these events, the plants were put into a safe configuration by the licensed operators, and fuel failures were prevented.

Following the failure to scram at Browns Ferry Unit 3, BWR plant operators were required to establish two SDV tanks (one for each bank of control rods) to mitigate the possibility of a hydraulic lock. A hydraulic lock could prevent control rods from inserting if the SDV tank is filled with water and causes blockage. This was the cause of the failure to scram at Browns Ferry Unit 3.

Following the Salem event, Westinghouse PWR plant operators were required to provide redundant means of automatically opening the trip breakers. The original Westinghouse design provided only one means by which the RPS would open the reactor trip breakers. In the aftermath of the Salem events, trip breaker operation was modified so that the RPS de-energizes both the trip breaker and the bypass breaker when trip logic is satisfied (see [Reactor Protection System](#)). The bypass breaker is used to allow testing of the trip breaker in each train during power operation without actually causing a reactor trip.

Following the LaSalle Unit 2 instability event in 1988, the BWR industry added measures to protect the reactor from power and flow instabilities and the possibility of fuel damage due to unmitigated power and flow oscillations. Some of these measures include additional trip signals as part of the Average Power Range Monitor (APRM); for example, addition of an Oscillation Power Range Monitor (OPRM) which scrams the reactor on indications of power oscillation. Also, the operating domain was limited, depending on the power density of the reactor. Additional modifications to these systems have also been required as part of licensee requests for increases in rated power and for additional flexibility with respect to the range of power and flow conditions in which the reactor may be operated.

As discussed in [Gaunt \(2021\)](#), licensees are now required to analyze ATWS events. These beyond-design basis scenarios are analyzed to evaluate the adequacy of proposed additional countermeasures to assure that the event can be safely terminated, and the plant brought to a safe, stable condition.

ATWS rule and plant modifications

In response to the failure to scram event at Browns Ferry Unit 3, the ATWS events at Salem Unit 1, as well as analyses of transients considered in probabilistic risk assessments, several NRC actions were initiated (Rempe, 2021b). In 1984, the NRC published 10CFR50.62, which is commonly referred to as “the ATWS rule” (NRC, 1984). This rule imposed new equipment requirements for all light water reactors, several which directly impacted the RPS design. The basis for the changes required by the ATWS Rule were based on analyses that showed a disproportionate risk for some plant designs. The basis for these changes, as well as typical modifications implemented within PWRs and BWRs are described here.

PWR

The ATWS rule required that some hardware modifications and operating limitations be implemented at all PWRs. However, the specific required changes varied amongst the three PWR reactor vendor designs discussed in this article (Westinghouse, CE and B&W).

CE and B&W designed PWRs were required to have a second, diverse trip system. The system was required to be independent of the RPS from the sensor outputs to the control rod drive mechanisms (CRDMs) power supplies. The diverse trip system has been imposed as a defense-in-depth measure for CE and B&W plants because of the relatively high percentage of fuel cycle time those plants are expected to operate with positive or only slightly negative Moderator Temperature Coefficient (MTC). This is also referred to as Unfavorable Exposure Time (UET). This was done in accordance with analyses performed by the reactor designers at the time of the ATWS rule. If an ATWS occurs during a period of UET, analyses predicted that existing mitigation systems are likely to be ineffective to limit the reactor power and the associated increase in reactor coolant pressure. Westinghouse designed plants have been excluded from this requirement because of their larger pressurizer safety valves and relatively smaller expected percentage of fuel cycle time with a positive or only slightly negative MTC (NRC, 2008a).

The original Westinghouse design provided only one means by which the RPS would automatically open the reactor trip breakers: de-energizing of the undervoltage coils. As noted in [Prior Events](#), trip breaker operation was modified to provide redundant means of automatically opening the breakers after the ATWS events at Salem Unit 1.

For all PWR plants, an ATWS Mitigation System Actuating Circuitry (AMSAC) was installed that starts the auxiliary feedwater pumps and trips the main turbine if indications of a loss of feedwater are present (i.e., steam generator levels drop below a low

level setpoint or the main feedwater flow drops below a predetermined setpoint). The AMSAC circuitry is only functional when the power level is greater than 40% of nominal.

The pressure relief capability was found to be important in preventing reactor coolant system (RCS) overpressurization during periods of UET for Westinghouse plants. Therefore, a Technical Specification was developed that limited operation with pressurizer power operated relief valves blocked during periods of UET.

BWR

The ATWS rule also required a number of changes to BWR systems and equipment (NRC, 2010). To increase the reliability for reactor scram, the rule required that an Alternate Rod Insertion (ARI) system be added that is diverse from the reactor trip system. This ARI system vents air from redundant scram valves to ensure that control rods are inserted.

A transient with failure to scram from full power is most severe for scenarios in which the reactor is isolated from the main turbine (e.g., after the turbine trips or after the main steam isolation valves (MSIVs) close). If the recirculation pumps continue to run, the power level will remain high and a severe pressure excursion will take place. Even if the RCS survives the pressure surge, the very high steam flow will rapidly heat the suppression pool and pressurize the containment. In addition, the High-Pressure Coolant Injection (HPCI) System (BWR/2–4 plants) or High Pressure Core Spray (HPCS) System (BWR/5–6 plants) may not suffice to cool the core: overheating and fuel damage may follow. Ultimately, the containment is expected to rupture due to over pressure while the core sustains damage. Continued core coolant replenishment is questionable after containment rupture. A large radiological release is a plausible outcome. Therefore, changes were mandated.

One necessary mitigating feature identified is a prompt automatic trip of the recirculation pumps to avoid the pressure excursion and diminish the power associated steam flow to the suppression pool. The rule required that additional logic be added to trip the recirculation pumps under ATWS conditions (high RPV pressure, low RPV water level). Given a trip of the recirculation pumps with no (or only a few) control rods inserted, the reactor power will stabilize at roughly 30% power until the reactor coolant boils down and steam bubbles (voids) form in the core. Thereafter, an oscillatory equilibrium will be maintained in which the reactor sustains the average power (up to about 30% power) necessary to boil off as much reactor coolant as is delivered. Analysis shows that HPCI/HPCS or main feedwater can adequately cool the core to avoid extensive fuel damage. However, if the reactor is not tripped, the energy delivered to the suppression pool will be greater than its cooling system can dissipate, resulting in an increase in pool temperature. If the suppression pool temperature increase is not mitigated, core overheating or containment over-pressurization could occur.

Containment over-pressure failure remains a distinct possibility unless the reactor is shutdown, either by control rod insertion or by liquid reactivity poison injection. Well before the containment is significantly pressurized, the suppression pool will approach saturation and steam condensing will begin to cause oscillations (also referred to as chugging or dynamic instabilities) (Marks and Andeen, 1979). These condensation oscillations create pressure impulses and dynamic loading of structures which may threaten containment integrity or pressure suppression structures, shortening the time available to safely shutdown the reactor. Also, because the HPCI/HPCS is a single-train system, the fault or human error that precipitates the initial transient might disable the HPCI/HPCS resulting in a loss of all emergency coolant injection capability.

In addition, system reliability analyses have indicated that HPCI may fail or be unavailable in as many as 1% of the cases in which a demand is made of the system. This may be insufficient reliability for mitigating a potentially serious accident having a frequency of occurrence that might be as high as once in a thousand reactor years. A second diverse system, the Reactor Core Isolation Cooling (RCIC) System should be expected to auto start and run, delivering coolant to the reactor. If RCIC is the sole operative means of replenishing reactor coolant, the adequacy of core cooling, rather than the heat deposited in the suppression pool, is likely to be the factor limiting the time allowed to safely shut down the reactor.

The RCIC can successfully cool the reactor once it is shut down, and it can slow reactor coolant boiloff. The two trains may be the HPCI/HPCS and RCIC. BWR/2 designs and older BWR/3 designs do not have RCIC systems. Instead, these designs have isolation condensers (either one or two depending on the design), which through pressure and gravity feed, can remove energy from the RPV on the order of what RCIC injection can provide.

The ATWS rule required that each BWR has a Standby Liquid Control (SLC) system with procedural actions for manual initiation to ensure injection of poison at a satisfactory rate (equivalent to 86 gpm/19.5 m³/h of naturally occurring Boron-10). The NRC has concluded that the liquid reactivity poison injection system in BWRs must have a start time and poison injection rate such that either of two redundant trains of high pressure reactor coolant replenishment systems, either of which may be expected to be available under ATWS conditions, can successfully mitigate ATWS transients. Some BWRs had SLC pumps that could inject at that rate, while other BWRs increased the Boron-10 enrichment of the solution used in the SLCS system to provide the equivalent rate of boron injection.

Reductions in unplanned scrams

Finally, for both PWRs and BWRs, a scram reduction program was initiated in 1985 by the industry (under the auspices of the Nuclear Utility Management and Reliability Committee) to reduce the annual number of unplanned plant scrams in order to reduce the demands for automatic scram features (NRC, 2000a,b). This program was successful in reducing the annual average annual number of unplanned scrams from over 5 to less than 0.5 between 1985 and 1998 (NRC, 2000a). As stated in NRC (2000b), the BWR Owners Group goal is less than 0.7 unplanned scrams per year. This was primarily achieved through improved

maintenance policies and training to reduce scrams caused by plant maintenance and surveillance activities while the plant is at power and by moving some maintenance and surveillance to when the plant is shutdown.

A decrease in unplanned scrams reduces challenges to the safety equipment and increases plant availability for electricity production. A major benefit is a reduced chance of damage to plant equipment due to operation in undervoltage conditions. Unplanned scrams create a transient on the offsite power grid which can result in significant voltage changes; undervoltage is a significant threat to operating electrical equipment.

Reactor protection system

Designs for the RPS, which include the scram systems have evolved with time. Descriptions of typical designs, which include the modifications discussed in **Anticipated Transient Without Scram (ATWS)**, found in Westinghouse PWRs and General Electric BWRs are provided here.

PWR

RPS designs differ amongst the Westinghouse designed plants. The most common designs are the relay protection system and the solid-state protection system. Either of these systems performs the same functions, with the solid-state protection system being more recent. Some plants have upgraded portions of their solid-state protection systems to include an innovative feature, an on-line, self-testing protection system. Using solid-state devices, this system checks the entire protection system continuously, regardless of the operational condition of the reactor.

The RPS solid-state design has significant improvements over earlier designs. Approximately 750 relays with 4000 contacts connected in various matrices were contained in the earlier RPS designs. Around fourteen 30-in. (76 cm) wide by 30 in. (76 cm) deep cabinets were required to accommodate these relays and contacts. The newer solid-state design only requires six of these cabinets. The addition of the self-testing circuit reduces the test time for the logic section of the protection system, the portion of the system that controls its response, from 4 h per train to approximately 1 h per train.

Fig. 2 shows a simplified diagram of a typical solid-state RPS for actuating a reactor trip or an engineered safety feature (ESF). Note that while every set of signals that generates an ESF actuation also generates a reactor trip, not every reactor trip generates an ESF actuation. This system, similar to the analog RPS, is comprised of two redundant, identical trains (A and B) that are physically separated and electrically independent. Inputs into this system are derived from various nuclear and non-nuclear sensors located both inside and outside of the containment building. Most of these signals are processed in the analog cabinets and result in bistable (B/S) outputs (i.e., the device can be in either an “on” or “off” position; 125 V ac when on, or zero volts when tripped) to the solid-state logic cabinets. Other protection signals are derived directly from the status of contacts at sensors or components (examples are oil pressure switches on the turbine, auxiliary contacts on circuit breakers, and limit switches on valves).

Logic

As shown at the top of **Fig. 2**, power to the CRDMs is supplied by motor generator sets through two series of reactor trip circuit breakers (“Train A” and “Train B”). The opening of either reactor trip breaker de-energizes all CRDMs, and the reactor trips by allowing the control rods to fall into the core by gravity. This trip scheme is an example of one-out-of-two logic; it requires the actuation of only one protection train and the opening of only one reactor trip circuit breaker, at a minimum, to trip the reactor.

While this logic provides redundant means for generating a reactor trip, reactor trip circuit breaker testing would scram the reactor without some compensating measure. Because testing is required, the RPS design includes bypass breakers for each train (“A” and “B” bypass breakers in **Fig. 2**) that are manually racked in (i.e., connected to the trip circuit) during testing. For example, if a test of the Train A reactor trip breaker is required, the “A” bypass breaker is racked in to provide a circuit path parallel to that of the Train A trip breaker to ensure continuity of power when the trip breaker is opened. The Train A bypass breaker is opened by the Train B protection train; therefore, during testing, the RPS is reduced to one-out-of-one logic.

As shown on the left of **Fig. 2**, the protection system consists of a number of analog channels for a given parameter. The analog section receives input signals from transmitters in each channel that sense process parameters. Each process signal for each channel is compared to a setpoint in this bistable (B/S) device. If the monitored parameter’s input signal is equal to or exceeds the setpoint, a trip signal for that channel is generated by the bistable. The bistable trip signal is sent to redundant logic cabinets (“A” and “B” trains), where the reactor trip actuation signals are generated.

Each reactor trip function (i.e., the parameter that can generate a reactor trip) has a coincidence network. Coincidence refers to the condition that more than one bistable trip signal for a given parameter needs to be present. In the center left of **Fig. 2**, only one such coincidence network is shown in each protection cabinet. In these cabinets, there are four channels monitoring a plant parameter, and the coincidence network has a two-out-of-four logic (i.e., input from at least two out of the four bistables/channels must be zero volts a.c.). For example, assume that the instrument transmitters are supplying pressurizer pressure signals. If instrument channel 1 (shown in red) senses a high-pressure condition (greater than the high-pressure trip setpoint), its associated bistable trips (i.e., supplies zero voltage to the logic cabinets). Both logic cabinets receive this signal and open the contacts associated with this channel. If no other contacts are open in this logic matrix, the undervoltage coils remain energized, and no trip occurs. If another

Fig. 2 Typical solid-state Westinghouse PWR reactor protection system. Taken from Fig. 12.1-2 of NRC (2009a) Westinghouse Technology Systems Manual. Section 12.1: Reactor protection system. US NRC Human Resources Training Development (HRTD). Available from <https://www.nrc.gov/docs/ML1122/ML11223A401.pdf>

transmitter also indicates a high-pressure condition, its associated bistable trips; thus, the necessary two-out-of-four logic is satisfied. When this occurs, vital power is interrupted to the undervoltage coils, allowing the reactor trip breakers to open.

Fig. 3 shows a simplified diagram of a typical relay protection system. This system features a significant number of relays for each protection function input as well as added complexity due to the test features. In **Fig. 3**, the red channel (Red I) is shown from the sensor of some parameter to the inputs to the logic cabinets. If this channel senses a pressure in excess of the setpoint value, its associated bistable trips, causing the bistable's output voltage to go to zero. With the bistable output at zero, the red input relays de-energize in both the Train A and Train B logic cabinets. When the input relays de-energize, the red contact labeled "1" opens in the logic matrix of Train A, and the red contact labeled "A" opens in the Train B logic matrix. The logic coincidence for this particular trip function is two out of four. Therefore, two channels must de-energize to produce a reactor trip. Note that even with the 1 and A contacts open, power is still delivered from the 125-Vdc battery buses to the undervoltage (UV) coils for the reactor trip and reactor trip bypass breakers.

A reactor trip does not occur unless at least one of the other three channels also senses the same condition, its associated bistable trips, and the associated input relays de-energize. With any two sets of logic matrix contacts open, power is interrupted to the undervoltage coils of the reactor trip breakers, causing them to open.

The logic cabinets receive the signal inputs from the protection bistables (either on or off). The bistable output signals provide the protection system inputs for all reactor trips and ESF actuations. Energized input relays 1, 2, 3, and 4 (for Train A) or A, B, C, and D (for Train B) hold their associated contacts closed, thereby maintaining continuity of power to the undervoltage coils of the reactor trip breakers. If an undervoltage coil de-energizes as the result of bistable trips, incorrect testing, or any other cause, one of the series connected reactor trip breakers opens, allowing all shutdown and control rods to fall into the core. The relay RPS is tested in a segmented fashion; the "push buttons" (e.g., PB1, PBA, etc.) shown in **Fig. 3** are a means to test individual parts of the logic when the reactor is at power without generating a reactor trip signal.

Fig. 3 Typical relay Westinghouse PWR reactor protection system. Taken from Fig. 12.1-1 of NRC (2009a) Westinghouse Technology Systems Manual. Section 12.1: Reactor protection system. US NRC Human Resources Training Development (HRTD). Available from <https://www.nrc.gov/docs/ML1122/ML11223A401.pdf>

Instrumentation inputs

The philosophy of the RPS is to define an area of permissible operation in terms of total power, flow, axial power distribution, and primary coolant temperature and pressure. The reactor is tripped when the limits of a selected area of concern are approached (NRC, 2009b). When the protection system receives signals indicative of an approach to an unsafe operating condition, the system actuates alarms, prevents control rod withdrawal if applicable, initiates a turbine runback if applicable (controlled decrease in turbine speed), and/or opens the reactor trip breakers. The instrumentation inputs to the RPS for a Westinghouse PWR are summarized in Table 1.

The overpower ΔT (OP ΔT) and overtemperature ΔT (OT ΔT) reactor trips provide core protection for situations in which:

- The transient is slow with respect to coolant piping delays from the core to the temperature sensors in the reactor coolant hot legs, and
- Pressure is within the range between the high- and low-pressure reactor trips.

The OP ΔT trip is designed specifically to ensure operation within the fuel temperature design basis. This is done through the OP ΔT by correlating core thermal power with the temperature difference across the reactor vessel hot leg and cold leg (ΔT). Because thermal power is not precisely proportional to ΔT (due to the effects of changes in coolant density and heat capacity), a compensating term, which is a function of average coolant temperature, is factored into the overpower trip setting. The OT ΔT trip is designed to ensure operation within the fuel rod heat transfer design basis and the hot leg boiling limit. Because both of these limits are functions of coolant temperature and pressure as well as core thermal power, the overtemperature trip is correlated with vessel ΔT , vessel average temperature, and primary system pressure.

The OP ΔT and OT ΔT protection function will trip the reactor when the compensated ΔT in any two channels exceeds the setpoint (three- and four-loop plants have one channel per loop; two-loop plants have two channels per loop). The temperature information for each channel (ΔT and T_{avg}) is obtained from independent pairs of resistance temperature measuring devices in the hot and cold legs of each loop. The setpoint for each channel is continuously calculated by analog circuitry programmed to evaluate the compensated OP ΔT and OT ΔT (Westinghouse, 1986).

Other reactor trips shown in Table 1, such as the low coolant flow and high neutron flux trips, provide core protection for accidents in which the loop ΔT signal does not respond quickly enough. Because the neutron flux measurement can span eight decades, three separate instruments are used: source range, intermediate range and power range. The source range is typically used to measure sub-criticality whereas the intermediate range is used during startup and shutdown; the power range is used during power operation (Young, 2021). Additional reactor trips, such as the high pressurizer water level and low feedwater flow trips, are provided primarily for equipment protection. Finally, some reactor trips, such as those produced by a turbine trip or reactor coolant pump circuit breaker opening, are provided in anticipation of potential plant transients and to minimize the resulting RCS thermal response of such transients.

The RPS design includes protection-grade interlocks (designated as P-n), also known as permissives, and control-grade interlocks (designated as C-n). An interlock blocks certain actions and permits others. Rod withdrawal stops are examples of control-grade interlocks; they are provided to prevent abnormal conditions which could result in a trip in response to excessive control rod withdrawal initiated by either a control system malfunction or a violation of administrative procedures by the operator.

Table 1 Representative Westinghouse instrumentation input to RPS (NRC, 2009b).

<i>Trip signal</i>	<i>Reason for trip</i>
Source Range High Neutron Flux	Prevents an inadvertent power increase
Intermediate Range High Neutron Flux	Prevents an inadvertent power increase
Power Range High Neutron Flux—low setpoint	Prevents an inadvertent power increase
Power Range High Neutron Flux—high setpoint	Limits maximum power to prevent damage to fuel rod cladding and fuel pellet centerline melting
High Positive Rate (of increase) Neutron Flux	Limits power excursions and prevents power distribution exceeding design basis
High Negative Rate (of decrease) Neutron Flux	Prevents power distribution exceeding design basis
Overtemperature ΔT (OT ΔT)	Prevents operation in excess of the fuel rod heat transfer design basis and the hot leg boiling limit
Overpower ΔT (OP ΔT)	Prevents operation in excess of the fuel temperature design basis
Pressurizer Low Pressure	Prevents operation in excess of the fuel rod heat transfer design basis and the hot leg boiling limit
Pressurizer High Pressure	Protects integrity of RCS pressure boundary
Pressurizer High Water Level	Prevents loss of pressure control due to solid water operations
Low Reactor Coolant Flow	Ensures adequate coolant flow to remove core heat and prevent fuel rod damage
Reactor Coolant Pump Bus Undervoltage or Underfrequency	Redundant to low reactor coolant flow trip
Reactor Coolant Pump Breaker	Redundant to low reactor coolant flow trip
Steam Generator Low-Low Level ^a	Prevents loss of heat sink
Low Feedwater Flow	Anticipates loss of heat sink
Turbine Trip	Prevents continued operation if steam load is lost to SGs
Safety Injection Actuation	Anticipates loss of reactor coolant

^aThere are two low-level setpoints for steam generator level. The first, called low level, is to alert the operators to an abnormal condition. The low-low-level is a potential loss of heat sink and generates a trip signal.

BWR

The most common BWR RPS design is an analog protection system with the addition of some solid-state protection system features, such as found in OPRMs and digital additions added to the APRMs logic.

The BWR RPS system is comprised of two redundant, identical trains (A and B) that are physically and electrically independent. Inputs into this system are derived from various nuclear and non-nuclear sensors located both inside and outside of the primary and secondary containment. Protection signals are derived directly from the status of contacts at sensors or components (examples are lubrication oil pressure switches on the turbine, auxiliary contacts on circuit breakers, and limit switches on valves).

Logic

The RPS is arranged in a one-out-of-two-twice de-energized-to-function logic scheme. Each trip system is completely independent of the other. The RPS logic consists of two separately powered trip systems (System A and System B). Each trip system contains two trip channel logics. The trip logics of system A are designated channels A1 and A2 and both receive at least one input signal from the same monitored parameter ("**Instrumentation Inputs**"); both trip channels are identical. Thus, any monitored parameter supplying an automatic trip signal has a minimum of four sensors. System B is identical to System A.

A signal from a sensor that exceeds the predetermined setpoint, either scram channel A1 or A2, causes a trip in system A. A trip condition in system A de-energizes the A scram valve solenoid for all 137 control rod HCUs. This condition is called a half scram. Likewise, any sensor in trip system B exceeding its setpoint (trip condition) causes a half scram. To produce a full reactor scram, both trip systems, A and B, must be in the trip (deenergized) condition.

In addition, two other methods are provided for manually causing a reactor scram. Two pushbuttons (one for System A and one for System B) are provided in the control room (one pushbutton per channel), each of which will de-energize its respective channel when pushed. De-energizing one channel in each trip system causes a manually actuated reactor scram. Placing the reactor mode switch into the "SHUTDOWN" position will also cause a manually actuated reactor scram by de-energizing all four RPS channels.

The six ARI solenoid valves are provided to redundantly depressurize the scram air header. These valves are divisionally separated with three assigned to the "A" division and three assigned to "B"; their logic is independent of RPS. Any condition resulting in a high reactor pressure (1120 psig/7.72 MPa-g) or low RPV level (−38 in./ −96.5 cm) will energize these solenoid valves to depressurize the header (the values given above are representative of smaller BWR/4's, values very slightly for other designs). The operator is also provided with capability for manual initiation of the logic.

Instrumentation inputs

Instrumentation input to the RPS for a representative BWR/4 is summarized in [Table 2](#). Similar to the PWRs, the goal of the majority of the instrumentation input to the RPS is to protect the integrity of the fuel rods in the reactor core and the integrity of the reactor vessel and connecting piping. However, several RPS inputs differ from those in a PWR owing to differences in BWR design features.

- Because of the small volume of the drywell, a reactor trip on high drywell pressure assures that primary containment integrity can be maintained in the event of a design basis accident.

Table 2 Representative BWR/4 instrumentation input to RPS (NRC, 2011a).

Scram signal	Reason for scram
High Drywell Pressure	Protect containment integrity (minimize energy containment must absorb)
Low Reactor Water Level	Protect fuel cladding from inadequate cooling (prevent fuel rod failure)
High Reactor Pressure	Protect reactor coolant boundary integrity (prevent loss of coolant)
Main Steam Line High Radiation	Limit further fission product release (prevent fuel rod failure)
Turbine Stop Valve Closure	Protect fuel cladding against positive reactivity insertion following void collapse in the core (prevent fuel rod failure)
SDV High Level	Allows RPS to scram while sufficient free volume exists in SDV tank to complete the scram
MSIV Closure	Protect fuel cladding against positive reactivity insertion following void collapse (prevent fuel rod failure)
Average Power Range Monitor (APRM) High-High Fixed Trip ^a	Protect fuel cladding against excessive power (prevent fuel rod failure)
APRM "Inoperable" Trip	Prevent continued operation with failed instrumentation
Intermediate Range Monitor (IRM) High-High Trip ^a	Protect fuel cladding against excessive power and short time intervals between power oscillations (Young, 2021) (prevent fuel rod failure)
IRM Inoperable Trip	Prevent continued operation with failed instrumentation
Source Range Monitor (SRM) High-High ^a	Protect refueling personnel from inadvertent criticality
SRM Inoperable	Protect refueling personnel from inadvertent criticality

^aThere are two high level setpoints for neutron flux monitors. The first, called "high," is to alert the operators to an abnormal condition. The "high-high" is a potential power excursion and generates a trip signal.

- Because the main steam lines provide a direct path between the reactor vessel and the turbine/condenser, a reactor trip on high radiation limits fission product releases to the atmosphere.
- Because the loss of voids in the coolant in the reactor core is a positive reactivity insertion event, reactor trips for loss of the turbine (stop valve or MSIV closure).
- Because the primary reactor trip strategy involves discharging water into the SDV, a reactor trip for high level in the SDV tank ensures that sufficient free volume still exists for this reactor trip strategy.

The setpoints for the reactor trips for these instruments depends on the mode of operation of the plant. The four principal modes of the RPS are: "SHUTDOWN," "REFUEL," "STARTUP/HOT STANDBY," and "RUN." The selection of the various modes is accomplished via a key lock selector switch appropriately called the reactor mode switch. The reactor mode switch interlocks the various control functions depending on the plant operating condition. The reactor mode switch is manually placed in one of the four positions which places into effect the corresponding trip functions for that mode.

Placing the reactor mode switch in "SHUTDOWN" initiates a reactor scram, disables the MSIV closure scram, and enables the capability to bypass of the SDV high level scram.

Placing the reactor mode switch in "REFUEL" disables the MSIV closure scram. The refuel position also enables the bypassing of the SDV high level scram and allows single control rod withdrawal to support refueling activities.

Placing the reactor mode switch in "STARTUP/HOT STANDBY" allows the operator to withdraw control rods for a plant startup and disables the ability to bypass the SDV high level scram. The MSIV closure scram is still bypassed. Some neutron monitoring trip functions are enabled while others are bypassed.

Placing the reactor mode switch in "RUN" selects the APRM thermal power scram and fixed scram trip level while removing the 15% power APRM scram. The IRM system scram signals are disabled except for the IRM Hi-Hi and companion APRM downscale scram. The MSIV closure scram is enabled.

Summary

Severe plant transients require that the reactor be shut down by the RPS. The RPS is designed to provide a highly reliable means of achieving reactor shutdown in the event of one of these severe transients by monitoring certain parameters; a means for the operators to manually scram the reactor from the control room or from the remote shutdown panel is also provided. Plant technical specifications are developed for the reactor scram system instrumentation to assure their operability and accuracy by means of various surveillance requirements.

The RPS designs for PWRs and BWRs are comprised of two redundant, identical trains that are physically and electrically independent. Inputs into this system are derived from various sensors located both inside and outside of the primary containment building. The RPS contains a logic section that requires instrumentation input from more than one instrument channel to generate a signal to automatically shutdown the reactor. This prevents a failure in a single instrument channel from shutting down the reactor. Automatic shutdown of the reactor is accomplished by removing electric power from a device that then passively inserts the control rods into the core. The PWR and BWR RPS designs meet all requirements of the NRC.

With respect to the RPS design, special consideration is given to their ability to prevent and mitigate ATWS events. In response to ATWS events and several failures of reactor scram systems at operating plants, the NRC imposed new requirements to further assure that reactors could be shutdown safely.

Glossary

BWR Boiling Water Reactor.

Design basis accident The range of events taken explicitly into account in the design of structures, systems and components and equipment of a facility such that the facility can withstand them without exceeding authorized limits.

Emergency operating procedure A set of instructions that are to be implemented following an unintentional reactor trip or safety injection initiation.

Emergency power bus The a.c. busses that are powered from offsite power but are also automatically energized by the emergency diesel generators when offsite a.c. power is not available.

Engineered safety feature (ESF) Those systems, structures and components (SSCs) that have a function to mitigate the consequences of an accident.

General design criteria The set of minimum requirements for the design and safety analysis for water-cooled nuclear power plants.

Guidance Any set of instructions that are recommended to be implemented under prescribed plant conditions.

Procedures A set of instructions that are *required* to be implemented verbatim under prescribed plant conditions.

Maximum hypothetical accident A major accident, hypothesized for purposes of site analysis or postulated from considerations of possible accidental events, that would result in potential hazards not exceeded by those from any accident considered credible. Such accidents have generally been assumed to result in substantial meltdown of the core with subsequent release of appreciable quantities of fission products.

Owners group A group of plant owners with similar plant designs (usually by reactor vendor or reactor type) that fund development programs common to their plant designs.

PWR Pressurized water reactor.

Reactivity A measure expressing the departure of a reactor system from criticality. A positive reactivity addition indicates a move toward supercriticality (power increase). A negative reactivity addition indicates a move toward subcriticality (power decrease).

Reactor trip/reactor scram An automatic actuation of systems to terminate the fission process in the reactor. The term, "trip," is typically applied to PWRs and the term, "scram," to BWRs.

Single failure criterion Requirement that a system which is designed to perform a defined safety function must be capable of meeting its objectives assuming the failure of any major component within the system or in an associated system which supports its operation.

System, structure and components (SSC) A term typically reserved for those design features of the plant that are important to safety.

Introduction

Engineered safety features (ESFs) and associated safety systems and procedures are the third level of defense-in-depth to prevent damage to the reactor core and releases of radioactivity requiring offsite protective actions and to return the plant to a safe state (IAEA, 2018; Rempe, 2021). In other words, any system, structure or component (SSC) that is specifically designed to function to mitigate the consequences of an accident can be classified as an ESF of the plant. Generally speaking, the term ESF is only applied to those systems and components used to mitigate design basis accidents. The ESFs are part of the overall Reactor Protection System (RPS) that is discussed in Lutz and Williamson (2021c). This section focuses on the SSCs; the procedures and guidance are discussed in Lutz and Williamson (2021a).

The very first commercial nuclear power reactors did not have ESFs as we know them today. At that time, there was a safety focus on the maximum hypothetical accident, which was then considered to be a catastrophic break of a large pipe in the system that provides cooling water for the reactor. This accident was considered to be of such low probability that dedicated systems with redundant components were not included in the design. In some cases, systems used to support normal operation of the plant were designed to serve double-duty in the unlikely event of an accident.

The development of General Design Criteria (GDC) for power plant construction brought about the first significant change in requirements for ESFs as we know them today (NRC, 1967). As discussed in Rempe (2021), the GDC were finalized in 1971 (NRC, 1971). Published as Appendix A of the NRC regulations in 10 CFR 50 (U.S. Government Printing Office, 2019), the GDC call for redundancy and diversity in engineered safety systems designed to protect the core in the event of a circumferential break in a main coolant pipe (i.e., the above-mentioned maximum hypothetical accident). The GDC also include a requirement for ESFs to prevent the containment from failing in the event of any loss of coolant accident (LOCA). The “single failure” criterion was introduced in the GDC as one of a set of tools for ensuring highly reliable SSCs are provided for safe shutdown and cooling as well as mitigation of design basis accidents (NRC, 1977).

The safety significance of the ESFs of that time, and the single failure criterion were demonstrated in the Reactor Safety Study, also known as WASH-1400 (NRC, 1975). The Reactor Safety Study lists five functions of ESFs for LOCAs:

1. Rapid shutdown of the reactor to limit core heat production,
2. Core cooling to prevent release of radioactivity from fuel,
3. Containment isolation to prevent dispersal of radioactivity to environment,
4. Removal of heat from containment to prevent overpressurization, and
5. Removal of radioactivity from containment atmosphere.

These ESFs were designed to reduce the amount of radioactivity released to the environment should either a LOCA or transient event result in a significant release of radioactivity from the reactor core.

The Reactor Safety Study notes that in early power reactors, the power level was about one-tenth that of the new larger reactors. Because the decay heat was low enough to be readily transferred through the steel containment walls to the outside atmosphere, it could not over-pressurize and fail the containment. Thus, if a LOCA were to occur, and even if the core were to melt, the low leakage containments that were provided would have permitted the release of only a small amount of radioactivity (see Addendum for a description of ESFs in earlier plants from the 1960s). The decay heat levels for the newer plants in the 1970s were so high that the heat could not be dissipated through the containment walls. Thus, new sets of requirements were imposed.

The Reactor Safety Study further confirms that dedicated Emergency Core Cooling Systems (ECCSs) were needed to prevent core melting which could, in turn, cause failure of all barriers to the release of radioactivity. Systems were needed to transfer the core decay heat from the containment to the outside environment in order to prevent the heat from producing internal pressures high enough to rupture the containment. Finally, systems were needed to remove radioactivity from the containment atmosphere in order to reduce the amount that could leak from the containment into the environment. The major goal behind these changes was to attempt to provide ESFs designed so that the failure of any single barrier would not be likely to cause the failure of any of the other barriers.

The Reactor Safety Study concluded that the probability of a large pipe break causing a core melt was much less likely than a small LOCA or a transient (without a pipe break), particularly the loss of offsite power followed by the failure of the auxiliary feedwater (AFW) system for decay heat removal. However, the Reactor Safety Study showed that the ESFs that were required by the GDC were, in part, responsible for the low probability of the maximum hypothetical accident leading to core melt. This result, in conjunction with the recently completed Emergency Core Cooling System Rulemaking (NRC, 1973; NRC, 1974; Rempe, 2021), shifted attention from the large break loss of coolant accident to the more probable small LOCA and transients in safety analysis.

The next major event that changed the course of ESFs was the core melt accident at Three Mile Island Unit 2 (TMI-2). This accident was initiated by a transient (loss of feedwater) that led to a small break LOCA but operator actions to prematurely terminate safety injection resulted in core damage (Rogavin and Framptom, 1980; Kemeny et al., 1979; Skillman and Rempe, 2021). As a result, the U.S. NRC issued new requirements for licensing nuclear power plants (NRC, 1980a,b). Of the numerous new requirements, those dealing with the AFW system and relief valves would fall under the broad classification of ESFs. Other new requirements involved instrumentation and emergency procedures, as discussed in Lutz and Williamson (2021a,b).

For PWRs, the new requirements for AFW included: automatic initiation of feedwater injection on either low SG level or reactor trip; loading motor-driven AFW pumps onto emergency power busses; and that no single failure would result in a loss of AFW function. There were also new requirements for indication of open safety or relief valves.

For BWRs, the new requirements included diverse and redundant indications of the position of safety overpressure relief valves and logic changes to Reactor Core Isolation Cooling (RCIC) to automatically restart after trip on high Reactor Pressure Vessel (RPV) water level.

Based on the results of the Reactor Safety Study, as well as operating experience at nuclear power plants, the NRC imposed an additional set of requirements for the AFW system in 1988 that required the capability to cope with a loss of all a.c. power to the plant (NRC, 1988). The duration of the loss of a.c. power for each plant was based on a number of factors including previous events resulting in a loss of offsite a.c. power.

Engineered safety features (ESFs)

The NRC requires certain SSCs to be identified as ESFs, including the primary containment structure, containment systems, residual heat removal (RHR) systems, ECCSs, containment heat removal systems, containment atmosphere cleanup systems, and certain cooling water systems (NRC, 2007, 2019). Other systems that have design and testing requirements similar to these ESFs are covered by other regulatory requirements. These include the AFW system, emergency power supply and cooling water supply. They are included in this discussion based on the similarity of requirements to the ESFs.

The SSCs included in this discussion are listed in Table 1. Acronyms in the table are defined within this chapter.

Core subcriticality

Establishing and maintaining core subcriticality is not always thought of in terms of ESFs, but there is redundancy and diversity in the systems used to establish and maintain core subcriticality following an accident as required by the U.S. NRC's GDC (NRC, 1971).

In LWRs, the first line of defense in establishing core subcriticality is the negative reactivity supplied by prompt reactor control rod insertion and borated water injection.

Pressurized water reactors

A combination of boric acid in the reactor coolant system (RCS) and control rod position is used to control reactor power during full and partial power operation. For planned shutdowns, a combination of insertion of all control rods and increased boric acid

Table 1 Systems, structures and components considered as engineered safety features.

Function	Method	PWR SSCs	BWR SSCs
Core Subcriticality	Negative Reactivity	PWRs (Control Rods, Boron)	BWRs (Control Rods, Standby Liquid Control)
Core Heat Removal	Water Injection	PWRs (ECCS-HPSI, LPSI, Accumulators)	BWRs (ECCS-HPCI, LPCI, Core Spray, LPCF)
	Heat Removal	PWRs (Heat Exchangers - for cooling water recirculation, and AFW)	BWRs (Suppression Pool, SRVs, ADS)
Emergency Power	Pressure Control	PWRs (PORVs and ARVs)	BWRs (SRVs, ADS logic)
Prevent Radioactivity Release from Containment	Pressure	PWRs (DGs, Batteries)	BWRs (DGs, Batteries)
	Suppression	PWRs (Primary Containment, Volume, Sprays, Ice Condensers)	BWRs (Drywell Volume, Drywell Sprays, Suppression Pool sprays and cooling)
	Heat Removal	PWRs (Sprays, Fan Coolers)	BWRs (Drywell Sprays -some BWRs do not have Drywell sprays, fans, coolers)
	Isolation	PWRs (Isolation Valves)	BWRs (Isolation Valves and MSIVs)
	Fission Product Cleanup	PWRs (Sprays, Filters)	BWRs (Drywell Sprays, Suppression Pool Sprays)
	Hydrogen Control	PWRs (Igniters, Recombiners)	BWRs (Inerting, Igniters, Vent)
Heat Removal	Ultimate Heat Sink Water	PWRs (Component Cooling, Service Water)	BWRs (Closed Cooling Water System, RHR Service Water, Emergency Equipment Cooling Water)

concentration is used to establish and maintain subcriticality. In the event of a LOCA, a combination of the insertion of control rod clusters (the failure of one control rod cluster to insert is assumed in safety analyses) and borated water addition via the ECCS pumps is used to establish and maintain the reactor subcritical. Control rod insertion depends only on disconnecting the electrical power to the control rod drive grippers; boric acid injection is via borated water from one of two independent trains of ECCS (see “[Water injection and core heat removal](#)” section). For other accidents insertion of control rods combined with rapid boration establishes and maintains core subcriticality.

The anticipated transient without scram (ATWS) event is a special accident that is now considered after the issuance of the ATWS Rule (NRC, 2020). Changes to the plant ESFs to reduce the risk from ATWS events are discussed in [Lutz and Williamson \(2021c\)](#).

Boiling water reactors

A combination of adjusting the control rod position and core coolant flow rate is used during reactor power operation to control core power. For planned shutdowns, a combination of fully inserting control rods and reducing core flow is used to establish shutdown conditions. For a BWR with all control rods fully inserted, the reactor is shutdown and subcritical under all conditions.

The anticipated transient without scram (ATWS) event is a special accident that is now considered after the issuance of the ATWS Rule (NRC, 2020). Changes to the plant ESFs to reduce the risk from ATWS events are discussed in [Lutz and Williamson \(2021c\)](#).

Water injection and core heat removal

The water injection and core heat removal functions are served by the same ESFs. Water injection assures that the core is covered with water so that core decay heat can be effectively removed from the reactor fuel rods. Core heat removal assures that the decay heat removed from the fuel rods by the water is transferred to an ultimate heat sink outside of the primary containment structure.

For both PWRs and BWRs, the water injection and decay heat removal requirements vary over the range of LOCA break sizes, as well as for non-LOCA events. Large LOCAs are typically defined as breaks in reactor coolant pipes (or pipes connected to the reactor coolant pipes that cannot be isolated) greater than about 6 in. (15 cm) equivalent diameter, including the design basis double ended guillotine break of a large diameter reactor coolant pipe. Medium LOCAs are typically defined as coolant piping breaks between about 6 in. (15 cm) and 2 in. (5 cm) equivalent diameter. Small LOCAs are coolant piping breaks less than about 2 in. (5 cm) equivalent diameter. There is also a class of Very Small LOCAs which are coolant piping breaks less than about 0.5 in. (1.25 cm) equivalent diameter; these behave similar to non-LOCA events for the purposes of water injection and decay heat removal.

Breaks in the reactor vessel are not considered in the design basis because of the rigorous surveillance to detect and remedy cracks in these thick wall vessels. However, core cooling can be maintained for breaks in the reactor vessel up to the capability of the safety injection system to fill the reactor vessel above the top of the fuel.

Pressurized water reactors

Removal of decay heat from the reactor core involves different combinations of systems and components, depending on the event and the stage of the event. In general, there is an early “injection” phase that relies on the heat of evaporation of injected water to remove decay heat from the core to the containment and a later “recirculation” phase that relies on heat exchangers to cool water as it is recirculated from containment back into the core. The descriptions below pertain to Westinghouse PWR designs (NRC, 2006); differences for the other PWR designs are addressed in “[Other PWR designs](#)” section.

Safety injection system designs for LOCA events have both diversity and redundancy. There are two independent trains of low-pressure, intermediate-pressure and high-pressure safety injection to provide cooling water to the reactor core. Each train of safety injection is powered from a separate emergency power bus that is fed from redundant emergency diesel generators. Accumulators are passive components that inject their water when the RCS pressure drops below a predetermined setpoint. The safety injection system valves in these systems that are required to change position during the injection phase are check valves. The only motor operated valves are those required to switch from injection phase to recirculation phase; these valves are powered from the same emergency busses as the pumps in their respective trains.

Injection phase

Large LOCAs - For large LOCAs, the initial decay heat removal is accomplished with a combination of accumulators, high pressure safety injection (HPSI) pumps and low-pressure safety injection (LPSI) pumps (some plants also have intermediate pressure injection pumps). Water is injected into the RCS cold legs where it removes decay heat as it flows through the core and is discharged to the containment. The flow rates are not only sufficient to remove all decay heat from the reactor core but also to restore the water height in the reactor vessel to a level above the top of the core to maintain core cooling.

For the largest LOCAs, accumulators are needed to provide initial injection because of the delay in loading the injection pumps onto emergency busses if offsite power is lost. These accumulator tanks begin to inject when a single check valve opens as the RCS pressure decreases below a predetermined value (typically between 200 and 600 psig, or 1.4 to 4.1 MPa-g) and the pressure of the cover gas (nitrogen) forces the accumulator water into the cold legs. This water is followed by water injection from the HPSI and LPSI pumps.

Medium LOCAs - For medium size LOCAs, the RCS pressure may not drop below the shutoff head of the LPSI pumps and core cooling is accomplished using the intermediate pressure and HPSI pumps. This flow is sufficient to maintain core cooling while the break flow removes all decay heat from the reactor core and restores water level above the top of the core.

Small LOCAs - For small LOCAs, the RCS pressure remains high enough that only the HPSI pumps will discharge into the cold legs. In this case, the break flow is not sufficient to remove all of the core decay heat and refill the reactor coolant system; auxiliary feedwater to the steam generators is necessary to supplement the break flow in removing core decay heat. Without auxiliary feedwater flow for heat removal, the RCS pressure would steadily increase, and injection flow would not be able to maintain core cooling (injection flow from centrifugal safety injection pumps decreases as system pressure increases).

Transient Events - For the very small LOCAs and for transient (non-LOCA) events, heat is removed from the reactor core by the AFW system. Upon reactor trip, the main feedwater pump is tripped, and the AFW system is automatically started. The AFW system has the same redundancy (separate trains) and diversity (motor driven and a.c. independent pumps). The AFW system generally consists of two motor driven pumps and one turbine driven pump that take suction from a common tank (Condensate Storage Tank) and inject into the steam generators. The turbine driven pump is powered by steam from at least two steam generators (one steam generator supply source can be isolated in the event of a steam generator tube rupture to prevent releases of radioactivity).

For the response to an ATWS event, emergency operating procedures instruct the plant operators to fully open the AFW throttle valves (the throttle valves are manually set at a predetermined flow rate to prevent overcooling of the RCS for steam line break events).

Recirculation phase

When the water stored in a tank for safety injection is depleted, the suction for the safety injection pumps is switched to the containment sump, which collects water released from the break during a LOCA. The LPSI pumps take suction from this sump and either inject the water directly into the reactor coolant cold legs if the reactor pressure is low enough or they act as a booster pump for the HPSI pumps. The water drawn from the containment sump is passed through a heat exchanger before being injected back into the RCS. This is the primary means of long-term heat removal for LOCAs; for some plants, the heat exchanger is on the containment spray recirculation system but acts similarly in removing core decay heat.

In the recirculation phase for large break LOCAs, if the LOCA is in one of the cold legs it is possible for a portion of the injected water to flow around the core barrel and be discharged through the break directly to the containment without traveling through the core. The portion of the safety injection flow that does reach the core would remove decay heat by boiling with the resulting steam flowing out the break location in the cold leg. In this case, the boric acid in the injected flow that reaches the core would be continually concentrated in the reactor vessel as a result of the boiling process (i.e., the product of boiling is primarily steam with other additives left in the reactor vessel). To prevent the boric acid from reaching the saturation concentration where it could precipitate and potentially cause blockages in the core that would interrupt long term heat removal, a portion of the recirculation phase injection is routed to the hot legs where it would flow downwards through the core and dilute any concentrated boric acid. The timing of the switchover to hot leg recirculation is based on conservative analyses because there is no means of measuring boric acid concentration in the reactor vessel following an accident.

Other PWR designs

There are a few unique design details of ESFs amongst the reactor designs offered by the three original U.S. PWR vendors. The descriptions above pertain to the designs offered by Westinghouse Electric Corporation.

The Babcock and Wilcox safety injection system design (NRC, 2008a) includes HPSI and LPSI pumps as well as accumulators as discussed above for the injection phase. However, in the recirculation phase, only the HPSI pumps are used. This is different from the Westinghouse and Combustion Engineering designs in which the required Net Positive Suction Head (NPSH) for the HPSI pumps cannot be met with the containment sump water. For the Babcock and Wilcox design, the containment sump water can satisfy the required NPSH for the HPSI pumps.

The Combustion Engineering design (NRC, 2008b) does not include a heat exchanger in the safety injection recirculation phase. The heat exchanger is in the containment spray recirculation line. Therefore, the Combustion Engineering design requires continual operation of the containment spray in the recirculation phase to provide core decay heat removal. However, the heat exchanger can be used by the LPSI pumps if the alignment is changed (during shutdown cooling, this alignment is normally used). Westinghouse and Babcock and Wilcox designs can terminate containment spray in the recirculation phase if predetermined conditions for containment pressure and temperature are satisfied.

Boiling water reactors

Removal of decay heat from the reactor core involves different combinations of systems and components, depending on the event and the stage of the event. In general, there is an early "injection" phase that relies on the heat of evaporation of injected water to remove decay heat from the core to the containment and a later "recirculation" phase that relies on heat exchangers to cool water as it is recirculated from containment back into the core. The descriptions below pertain to General Electric BWRs (NRC, 2011).

Safety injection during LOCA events is accomplished with diverse and redundant systems. There are two independent trains of low-pressure, and high-pressure safety injection to provide cooling water to the reactor core. Each train of safety injection is powered from a separate emergency power bus that is fed from redundant emergency diesel generators. The valves in these systems that are

required to change position during the injection phase are check valves. The only motor operated valves are those required to switch from injection phase to recirculation phase; these valves are powered from the same emergency busses as the pumps in their respective trains.

For LOCAs, the BWR/2 through BWR/4 designs use a High Pressure Coolant Injection (HPCI) and Low Pressure Coolant Injection (LPCI), while BWR/5 and BWR/6 designs use High Pressure Core Spray (HPCS) and Low Pressure Core Spray (LPCS) which distributes the injected water over the top of the core. For transient events, the BWR/2 and some BWR/3 designs utilize the Isolation Condenser (IC) for response to transients. The remainder of the BWR/3 and all of the BWR/4 through BWR/6 designs utilize a RCIC system which employ turbine driven feedwater pumps. Both the IC and RCIC systems are single train standby systems for safe shut down of the plant. These systems are not considered part of the safeguards core cooling system and do not have a LOCA function.

Injection phase

Large LOCAs - For large loss of coolant accidents, the initial decay heat removal is accomplished LPCI/LPCS pumps. Water is injected into the RPV and removes decay heat as it flows through the core and is discharged to the primary containment. The flow rates are high enough to remove all decay heat from the reactor core and to restore the RPV water level to the top of the jet pumps to maintain core cooling. Some earlier BWR's (BWR/2's) do not have jet pumps and rely on Core Spray systems to remove all decay heat. For the largest LOCAs, pressure control is not needed as the RPV depressurizes due to the Large Break LOCA.

Intermediate Break LOCAs - For medium size LOCAs, the RPV pressure may not drop below the shutoff head of the LPCI / LPCS pumps and core cooling is accomplished using the HPCI /HPCS pumps in conjunction with the LPCI/LPCS pumps or using the Automatic Depressurization System (ADS) in conjunction with the LPCI or LPCS pumps. This flow is sufficient to remove all decay heat from the reactor core. The ADS functions as a backup for the HPCI/HPCS system.

Small LOCAs - For small LOCAs, the RPV pressure remains high enough that only the HPCI/HPCS pumps will inject water. In this case, the HPCI/HPCS flow is sufficient to remove all of the core decay heat. HPCI/HPCS also serves to depressurize the RPV so that the LPCI/LPCS pumps can provide injection. For the case where HPCI is not available, the ADS acts as a back up to rapidly lower RPV pressure to permit injection by the LPCI or the LPCS pumps.

Transient Events - For the Very Small LOCAs and transient (non-LOCA) events, heat is removed from the reactor core by the IC or the RCIC system and on the HPCI/HPCS. Upon the reactor scram, the IC or RCIC starts. HPCI or HPCS is the backup for IC and RCIC under these conditions. ADS is the backup for HPCI or HPCS.

Recirculation phase

Once the initial injection phase is completed, suppression pool cooling using the RHR system is started to remove the heat from the primary containment while injection at a lower rate continues. The suppression pool cooling flow passes through RHR heat exchangers where the energy is transferred to the ultimate heat sink. Some BWRs have a containment or drywell spray, which also uses the RHR heat exchangers to transfer heat to the ultimate heat sink. While Mark I and Mark II BWRs have this spray capability, only some of the Mark III containments have containment spray; those Mark III BWRs without spray capability rely on large fan cooler units in the primary containment to transfer heat to the ultimate heat sink. For station blackout events in which all a.c. power is lost, a hardened vent can be used to remove heat from the suppression pool as long as water levels can be maintained by fresh water injection by turbine driven pumps (e.g., RCIC or HPCI in Mark I and II containments); a new requirement following the Fukushima accident resulted in a new dedicated vent by the suppression pool and the wetwell. For station blackout events in which all A.C. power is lost, Mark III containments use a feed and bleed method to remove heat from the suppression pool.

Pressure control

Effective core heat removal requires that the pressure in the reactor vessel and associated coolant systems be controlled for several reasons.

If the reactor vessel pressure exceeds the design limit of the reactor vessel and attached piping, failures of the vessel or piping are likely to occur which could make an event worse. While a double ended rupture of piping attached to the reactor vessel is a design basis accident, the rupture of the reactor vessel itself is not a design basis event. The catastrophic rupture of the reactor vessel is considered a very low frequency event due to the stringent design and inspection requirements of the ASME code.

If the reactor vessel pressure exceeds the shutoff head of the safety injection pumps, those pumps will not be able to inject water in the case of an emergency event.

For both PWRs and BWRs, the ability to remove heat from the reactor using safety injection pumps and to efficiently transition to a cold shutdown state requires intentionally dumping steam to the atmosphere by opening relief valves on the steam lines.

Pressurized water reactors

Overpressure of either the reactor vessel and associated piping or the steam generator is mitigated by spring-loaded safety relief valves. These are designed and maintained in accordance with the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code (ASME, 2019). There are typically two safety relief valves capable of relieving pressure from the reactor vessel for any event involving a successful reactor trip. The pressure relief valves are situated in the gas space at the top of the pressurizer and are set to open just below the reactor vessel design basis pressure.

Pressure control is normally performed by the pressurizer spray in PWRs. However, this system is not safety related and does not have sufficient capacity to respond to accidents that require pressure relief of the RCS. Pressure relief for accident mitigation is provided by power operated relief valves (PORVs), except as noted below for some Combustion Engineering PWRs. These relief valves are separate from the spring-loaded safety valves for overpressure control except for some European PWRs that use a dual-purpose valve manufactured in France.

Plants licensed prior to about 1979 do not have safety related PORVs; for these plants, the PORV valve operators and electrical control systems are normally designed to non-safety related standards while the remainder of the valve is designed as a RCS pressure boundary. Westinghouse PWRs have two (and sometimes three) large capacity PORVs; CE plants have either 2 PORVs or no PORVs; B&W plants have one small PORV. For CE plants without PORVs, the safety related RCS pressure control function is performed by the Auxiliary Pressurizer Spray (APS) system (NRC, 1989).

For PWRs, pressure control in response to an accident is implemented by the licensed operators from the main control room. Specific procedures prescribe the use of these for reducing reactor vessel pressure following reactor trip from power operation.

Boiling water reactors

Overpressure of either the RPV or its associated piping is provided by spring-loaded safety relief valves. These are designed and maintained in accordance with the ASME Boiler and Pressure Vessel Code. The number of SRVs are plant-specific and capable of relieving pressure from the reactor vessel for any event involving a successful reactor trip. In some BWR plants, there are additional safety valves set to automatically open sequentially at different pressures if the SRVs do not limit RPV pressure satisfactorily. A sufficient number of SRVs exist that even if one is inoperable, BWRs are able to demonstrate margin to the design limit.

The SRVs are spring loaded for automatic overpressure control and can also be operated by the licensed operators from the main control room to manually reduce reactor vessel pressure. Specific procedures prescribe the use of these for reducing reactor vessel pressure following reactor trip from power operation.

Containment functions

There are two principal containment functions: containment integrity and containment fission product control. Containment integrity refers to leak-tightness during an event by controlling containment pressure and temperature, isolation of containment of piping carrying liquid or gas through the containment pressure boundary (i.e., containment penetrations), and containment hydrogen control to prevent a catastrophic containment failure. Containment fission product control refers to reduction in containment airborne fission products to minimize the potential for atmospheric releases.

Pressurized water reactors

Containment leak-tightness

All PWR primary containment structures (except the early PWRs mentioned in the Addendum) are low leakage structures made of steel and concrete. Fig. 1 compares features of typical PWR containments. A few PWR containments are a free-standing cylindrical steel shell, particularly the ice condenser containments. The steel shell is encompassed in a concrete structure with an annular volume between them. The more traditional PWR containment is a re-enforced concrete structure with a steel liner directly inside the concrete structure. The concrete structure provides protection for the reactor vessel and other equipment inside the containment from missiles (externally generated as well as internal missiles) and provides radiation shielding in the event of an accident that releases fission products to the containment. In both cases, the steel shell provides the low-leakage characteristics of the containment. The large dry containment design for a Westinghouse 4-loop PWR typically has a 2.5 million cubic foot or 70,800 cubic meter internal volume with leakage rates on the order of 2 cubic feet per minute (0.06 cubic meter per minute) at the containment design pressure of 50 psig (or 0.34 MPa-g). The internal volume is largely determined by the licensed reactor power level because design pressure must not be exceeded during the initial phase of a design basis large LOCA.

The subatmospheric containment is maintained at a strong vacuum during normal operation (e.g., 10 psia or 0.07 MPa). As a result, the containment internal volume can be about 10% smaller than the large dry containment design while leakage characteristics and design pressures are similar. Following an accident, the containment spray system, using chilled water at about 50 degrees F/10 degrees C is capable of quickly (e.g., within an hour) returning the containment to a vacuum state thereby stopping any leakage from containment.

The ice condenser containments rely on the ice in the ice chest to limit the peak containment pressure during the initial phase of a design basis large LOCA. This allows a design pressure of about 12 psig/0.18 MPa-g and an internal volume of approximately 1.8 million cubic feet/50,970 cubic meters.

Containment pressure and temperature control

Containment pressure and temperature control is accomplished by either removing heat from the containment atmosphere to the ultimate heat sink or by absorption of heat from the containment atmosphere by water sprayed into the containment or melting ice in an ice condenser containment.

The "large dry" containments typically have two diverse methods of removing heat to the containment: the containment spray system and the fan cooler system. In each case, there are two safety related trains of heat removal equipment, each powered from a different emergency a.c. power bus and a different cooling water train.

PWR Containment Designs Differ

Fig. 1 Comparison of typical PWR containments. Galyean W and Rempe J (2005) *Accident Progression Analysis (P-300)*, U.S. NRC, <https://www.nrc.gov/docs/ML1204/ML12044A213.pdf>, May 2005.

- The containment spray system has both an injection phase and a recirculation phase. In the injection phase, water is sprayed into the containment from a storage tank. The ambient temperature water absorbs heat from the containment atmosphere and falls into the containment sump. In Westinghouse and B&W designs, heat is removed from the sump water by the ECCS recirculation heat exchanger; in Combustion Engineering designs, the heat exchanger is part of the containment spray recirculation alignment rather than the safety injection recirculation alignment. In all three designs, the containment spray water is maintained at a reduced temperature compared to the containment atmosphere and effectively continues to remove heat from the containment atmosphere.
- The containment fan coolers are large ventilation units with a. c. powered fans drawing air past cooling coils that are supplied with water from the service water system. There are normally 4 to 5 of these units in the containment with 50% of the units capable of removing all of the decay heat from containment following a design basis accident.

The subatmospheric containments, which are held at about 5 psig/0.135 MPa-g vacuum during normal operation, have only containment spray available for controlling containment pressure and temperature. The original design of the subatmospheric containments used chilled water (e.g. 50 degrees F/10 degrees C) for containment spray injection. When combined with the initial pre-accident vacuum state of the containment, the chilled spray injection could return the containment to a vacuum condition within 1 hour. The containment spray system in recirculation mode would maintain the containment in a vacuum condition.

The ice condenser containment has an ice bed with a large amount of ice to condense the steam for a loss of coolant accident and maintain the containment pressure below the design basis pressure, which is only on the order of 12–15 psig/0.07–0.08 MPa. This is effective until the ice is depleted. The ice condenser containments also include containment spray and containment recirculation spray to maintain containment pressure below its design limit. The ice condenser has multiple doors that open when a pressure differential is created by the loss of coolant accident steam discharge, so it satisfies the redundancy requirements for ESFs.

Boiling water reactors

Containment leak-tightness

All BWR primary containment structures are low leakage structures made of concrete with an embedded steel liner for leak-tightness. The primary containment is composed of the drywell and the volume containing the water suppression pool. That volume is called the torus in the Mark I design and the wetwell in the Mark II and Mark III designs. Fig. 2 compares features of typical BWR containments.

BWR Containment Designs Differ

Fig. 2 Comparison of typical BWR containments Galyean W and Rempe J (2005) *Accident Progression Analysis (P-300)*, U.S. NRC, <https://www.nrc.gov/docs/ML1204/ML12044A213.pdf>, May 2005.

Containment pressure and temperature control

Any mass and energy released into the drywell, from either pipe breaks or relief valve discharge, can result in an increase in drywell pressure. The increased drywell pressure forces the steam and air mixture into the suppression pool water where the steam is condensed, thereby reducing the drywell pressure. In the Mark I and Mark II designs, drywell and the volume above the suppression pool water also has containment spray capability to further reduce pressure and temperature.

In the long-term, the containment pressure and temperature are controlled by transferring heat to the ultimate heat sink by the drywell and wetwell sprays. The sprays take suction from the suppression pool water and spray into the drywell or wetwell after passing through heat exchangers to remove the heat. In the event of a LOCA, drywell and/or wetwell sprays are manually initiated, according to emergency operating procedures, within 10 min of initiation of the event.

The Mark I and Mark II plants have a small drywell volume that can rapidly pressurize during an accident and therefore have a relatively high-pressure capability. The Mark III has a much larger containments volume but with a smaller pressure capability. The Mark III containment has large safety grade ventilation units with a.c. powered fans drawing air past cooling coils supplied with water from the service water system. Some Mark III containments also have containment sprays to aid in heat removal. Suppression pool cooling, using the RHR system, is used to remove decay heat once containment or drywell pressure is lowered by sprays.

Emergency power

All ESFs are powered from emergency a.c. busses. The emergency a.c. busses are divided into at least two independent divisions. All engineered safeguards equipment, such as pumps and motor operated valves in a safeguards train, is powered from the same emergency bus of the same division so that a failure of one emergency a.c. bus will not disable both trains for safeguards. The source for the emergency a.c. power busses are either offsite power or emergency diesel generators. The emergency a.c. power busses are always energized from the offsite power source. Upon loss of the offsite a.c. power source, a signal is sent to start the emergency diesel generators. Once the emergency diesel generators are running, safeguards equipment is sequentially loaded onto the busses by automatic sequencer to avoid an overload due to simultaneous starting of various safeguards pumps.

All safety-related instrumentation and control systems are powered from emergency d.c. busses. The emergency d.c. busses are divided into at least two independent divisions. As in the case of a.c. power, control power for all safeguards equipment in a safeguards train is powered from the same emergency bus to prevent failure of one d.c. bus from causing failure of safeguards functions. The emergency d.c. busses are normally powered from inverters that draw from the emergency a.c. busses. In some instances, emergency d.c. busses may draw directly from the station batteries which are kept at full charge by battery chargers powered from emergency a.c. busses. In the event of a loss of all a.c. power, the station batteries are available to power critical d.c. busses that were previously powered from inverters.

Cooling water

There are two key cooling water systems that support the ESFs: Component Cooling Water and Essential Service Water. Component cooling water is used to cool equipment and heat exchangers from which leakage of radioactive materials into the cooling water could result in a release of radioactivity to the environment in the event of an accident. Service water is used to remove heat from the component cooling water system using a heat exchanger between the two systems, as well as other safeguards equipment such as motors and room coolers. Thus, the component cooling water system acts as an intermediate cooling loop which gives up its heat absorbed from components potentially carrying radioactive fluids to the essential service water system. For example, the cooling water used for the heat exchangers in the ECCS is component cooling water. The essential service water system transfers heat to the ultimate heat sink. The service water system also has a non-essential service water loop that removes heat from non-safety grade equipment such as the main turbines.

There are at least two trains of essential service water and component cooling because they serve ESFs. The cooling water trains and the electrical power for these trains is arranged in such a way that failure of one train of cooling water will not result in the failure of an ESF.

Compressed air

If compressed air is used in the functioning of any ESF components (e.g., pneumatic valves), then safety related compressed air trains are required. As in the case of electrical power and cooling water, at least two compressed air trains are provided and arranged so that the failure of one train would not fail an ESF.

Summary

SSCs that have a function to mitigate the consequences of a design basis accident are classified as plant ESFs. These SSCs are subject to more stringent design requirements, as well as regulatory scrutiny, including the effects of a failure of a key component or interfacing system. These ESFs are also subjected to rigorous surveillance and testing to assure they can reliably perform their function.

The ESFs for LWRs include those SSCs that are required to return and maintain the plant in a safe, stable state following a design basis accident and prevent the release of radioactivity to the environment. These SSCs perform the functions of core subcriticality, core cooling, RCS/RPV pressure control, and primary containment pressure and temperature control.

Addendum

Early plants did not have many of the ESFs that we think of today as integral to nuclear safety. Three events had a profound influence on today's basis for ESFs:

- Licensing of second generation plants with higher power levels between 1965 and 1975
- WASH-1400, Reactor Safety Study that was published in 1975 ([NRC, 1975](#))
- The Three Mile Island Unit 2 (TMI-2) accident in 1979 ([Skillman and Rempe, 2021](#))

Two early plants in particular can be used to illustrate the differences in ESFs in the first generation of plants (the original designs of Yankee Rowe and San Onofre Unit 1). Also included is a brief discussion of the Zion and Indian Point Units 2 and 3 designs, which were completed in the 1960s. Note that this information is based on personal experience of the authors of this chapter. A detailed search of the open literature could not identify any sources to validate this information. Please use this at your own risk.

Yankee Rowe (Operated 1961 to 1981 – Construction began in 1958): The original design had a single train low pressure ECC system (100 psi shutoff head) to guard against a large break LOCA (See Maximum Hypothetical Accident identified in WASH-740 ([AEC, 1957](#))) and two high pressure make-up pumps of about 30 gpm each. There was no provision for ECCS recirculation. There was also no provision for emergency feedwater (EFW) until after TMI-2. After TMI-2, EFW was implemented with three 50% capacity trains. The plant was continually upgraded in a piecemeal fashion so that it met regulatory requirements until it was shut down in 1981.

SONGS -1 (Operated 1968 to 1992 – Construction began in 1964): The original design did not have a dedicated ECCS to guard against large pipe breaks. Main feedwater could be connected (single train) to the RCS and a method of boration devised to provide protection against large pipe breaks in the RCS. Like Yankee Rowe, it did not have an AFW system until after the TMI-2 accident. It is not known if upgrades were made for RCS water injection. SONGS-1 was permanently shut down in 1992.

Zion (Operated by Commonwealth Edison from 1973 to 1998/ Construction began in 1968), Indian Point Unit 2 (Operated by Consolidated Edison from 1974 to 2020/Construction began in 1966), and Indian Point Unit 3 (Operated by the Power Authority of the State of New York from 1976 and presently operating in 2020/Construction began 1968): Zion and Indian Point Units 2 and 3 were really the fore runners of the second generation of nuclear plant designs in the USA. Due to their proximity to large population centers in Chicago and New York City, several additional safety features were required. Redundant and diverse safety systems were included in the design basis, some of which were not required by the NRC for plants in less densely populated areas. Following

the TMI-2 accident, the plant operators of Zion and Indian Point Units 2 and 3 commissioned plant specific full PRAs that included external events, such as earthquakes and fires (ComEd, 1981; ConEd and PASNY, 1981) to compare the “risk” from these plants to that for the reference plant used in WASH-1400 (NRC, 1975).

Results from these PRAs indicated that the ‘risk’ from each of these units was less than the reference plant evaluated in WASH-1400 (NRC, 1975). The designs for ESFs for the Zion and Indian Point plants were significantly different than the ESF design for the reference plant used in WASH-1400. There were also advances in PRA methodologies for these studies that led to more realistic results. The NRC and their contractors performed an in-depth review of the methodologies used (NRC, 1982, 1984) and concluded that there were no significant omissions or errors. In the case of Indian Point Units 2 and 3, the NRC subsequently concluded that that neither unit was a risk outlier and therefore neither shutdown nor imposition of additional remedial actions was warranted (NRC, 1985). The NRC came to the same conclusion with regard to the Zion plant although no reference could be found.

These units had two unique features to reduce fission product leakage from the primary containment that are not found on most other PWRs:

- A dedicated ESF to assure containment isolation by pressurizing the pipe volume between the inside and outside containment isolation valves (Isolation Seal Water System for liquid penetrations and Penetration Pressurization System for air and gas penetrations). These systems provided an extra measure of isolation in the event that the isolation valves would leak following an accident. These systems were unique to the Zion and Indian Point Units 2 and 3 due to their proximity to high population areas.
- A fission product removal mechanism on each of the two diverse containment heat removal systems. A chemical additive was included in the containment spray system to raise the pH of the spray water to enhance removal of radioactive iodines by the spray droplets and retain them in the containment sump. The containment fan coolers included High Efficiency Particulate Air (HEPA) and charcoal filters for removal of radioactive iodines, including organic iodines. While many PWR primary containment buildings included these diverse containment heat removal systems, the charcoal filters for iodine removal were unique to the Zion and the Indian Point Unit 2 and 3 plants due to their proximity to high population areas.

Introduction

Few people work under the 5-acre (2 ha = 20,000 m²) roof of a nuclear power plant. Beyond the confines of the control room, one's first impression might well be that the place is deserted; to a major extent, the plant runs itself. Most of the human effort required to monitor and adjust the plant systems is exerted in the control room, which can be either disconcertingly quiet or very much alive with signals and alarms. During plant operation, small groups of workers go about their business of performing surveillance and routine maintenance on the myriad of plant equipment, including calibration of instrumentation. Operators in the control room stay in touch with anyone out in the plant by means of a paging system.

There are two basic functions of instrumentation in a nuclear power plant—those needed for production of electricity and those needed for safe operation. The former might include turbine generator parameters and electrical distribution parameters for non-safety systems and equipment. The later include all of those associated with the reactor and its cooling systems as well as operation of engineered safety equipment and of systems to monitor radiation levels and maintain radioactive barriers. This article is focused on those needed for safe operation of the plant.

Nuclear physics, as all science, is logical, and those instruments are speaking the truth to anyone logical enough to recognize it. Defeat awaits the individual who even subconsciously ascribes human qualities like crankiness to functioning meters and thermocouples simply because they are bringing bad news. The answer in science is never to shoot the messenger (Rogavin and Frampton Jr., 1980).

The operators have all the information needed for safe operation of the plant by monitoring various parameters (pressures, temperatures, flows, levels, etc.) of various plant systems via instrumentation. This gives an indication of the plant "health";

operators can initiate many actions from the control room to maintain these parameters within predetermined ranges. When plant parameters exceed a predetermined value (either too high or too low), alarms sound and lights flash on the alarm panel in the control room to alert the operators of an unacceptable condition. These are driven by what the instruments sense is happening in the plant. The plant operators continuously observe information presented by the instrumentation and make note of trends that might permit them to take action before these alarms sound. In some cases, multiple alarms may announce nearly simultaneously making it difficult to immediately draw any sort of rational picture of something happening out in the vast plant.

Under abnormal or accident conditions, the instrumentation also provides input to automatically actuate protection systems if predetermined values for some parameter values are exceeded. The automatic actuation of the Reactor Protection System (RPS) provides rapid shutdown of the reactor. The RPS actuates a reactor trip by causing the control rods to be inserted into the core; this is sometimes called the Reactor Trip System (RTS). The RPS may also cause the automatic actuation of the Engineered Safety Features (ESF) to provide rapid starting of emergency water injection and cooling to protect the reactor core. The RPS and ESF are discussed in detail in [Lutz and Williamson \(2021a,b\)](#).

The components and systems that make up the instrumentation and control (I&C) function provide defense in depth which includes the use of redundancy, diversity, separation and fail-safe behavior. In some references, the control function refers only to those functions not related to safety; the control function of instrumentation related to safety is referred to as the protection function. In this article, I&C refers to the safety related protection function of instrumentation.

Redundancy provides protection against independent single failures and prevents a random independent failure in one component or system from disabling the desired function. Several similar instrument channels may be used to measure the same physical variable, and a logic decision is then applied to the redundant signals to identify and discard an erroneous channel. Each channel has its own independent power supply to ensure that a common power supply fault will not prevent the measurement of the variable.

Diversity is the use of two or more physically or functionally different means of performing the same function. It protects against certain types of common mode failures, such as those arising from design or maintenance errors. Diversity can be provided by the use of equipment and software of different designs or origins to carry out the same function. Failures due to errors in the design of one system thus do not affect the performance of the other.

Separation refers to the use of physical separation such as barriers or distance. Separation provides protection against common mode or cross-linked effects, such as fires and missiles, and prevents a fault from migrating from one system to another.

The failure-to-safety or fail-safe principle is widely used in I&C systems important to safety. In principle, equipment is selected and designed with a strong bias towards a certain output signal in the event of failure. A classic example of this principle is applied to motor and pneumatically operated valves in which failure of the electrical or pneumatic system causes the valve to either open or close.

However, electronic and computer-based components and equipment can have unknown software errors that might not be identified for all possible situations during software verification and must be used with care.

Historical events

The instrumentation in a modern nuclear power plant is a product of regulatory and industry standards that have been developed as a result of historical events in which instrumentation deficiencies have played a role. Regulatory standards refer to rules that have been developed by national regulators such as the US Nuclear Regulatory Commission (NRC); this includes standards developed by the International Atomic Energy Agency (IAEA) and the Western European Nuclear Regulators Association (WENRA). Industry standards refers to mandatory standards developed by industry groups such as the Institute of Electric and Electronic Engineers (IEEE). In some cases, regulatory standards endorse industry standards with clarifications when appropriate. For example, NRC Regulatory Guide 1.97 ([NRC, 2019](#)) endorses IEEE-497 ([IEEE, 2016](#)).

A concise history of the role instrumentation played in nuclear plant accidents can be found in [EPRI \(2015\)](#). Details for several key events that have had a significant impact on instrumentation systems follows.

Three Mile Island Unit 2 accident

On March 28, 1979, a loss of feedwater event occurred at the Three Mile Island Unit 2 (TMI-2) resulting in a core meltdown that was partially caused by deficiencies in instrumentation as well as the operators' understanding of the feedback provided by instrumentation ([Skillman and Rempe, 2021](#)). In this case, a pressurizer relief valve failed to re-close, but the instrumentation indicated that it was indeed closed (the instrumentation was based on control power and not valve position). The pressurizer water level started to increase as the gas bubble in the top of the pressurizer was lost and the coolant pressure started to drop as a result of the open relief valve. Safety injection was automatically initiated by the instrumentation indicating low coolant pressure, but the operators turned off safety injection because the indicated pressurizer water level was too high and rising. The core continued to overheat as the operators tried to make sense of the various instrument readings and missed several opportunities to conclude that the core had been badly overheated. High reactor coolant system (RCS) hot leg temperatures and high core exit thermocouple temperatures indicated a severely overheated core, but this information was "dismissed." Similarly, a rising core neutron flux indicated that the core was slumping downward, but no one was able to assimilate this information to a correct diagnosis. Other instrumentation data

including containment pressure, containment radiation levels, containment sump water levels and radwaste radiation levels were not considered in the diagnosis until the accident was essentially arrested.

The ways that instrumentation contributed to the accident are detailed in NUREG-0660 (NRC, 1980a) and NUREG-0737 (NRC, 1980b). Significant changes in the requirements for instrumentation were made as a result of the requirements in both Regulatory Guide 1.97 Revision 2 (NRC, 1980c) and IEEE Standard 497-1979 (IEEE, 1977). There were also significant changes made in the display of certain post-accident plant parameters (called the Safety Parameter Display System or SPDS) in the main control room (NRC, 1980d). Additionally, there were requirements for new facilities, a Technical Support Center (TSC) and an Emergency Offsite Facility (EOF), in which the SPDS would be available for plant emergency response staff to perform independent assessments of the plant conditions and trends.

In conclusion, while there were some deficiencies in instrumentation itself, the more important deficiency was in understanding what the instrumentation was trying to tell the operators. This led to improved emergency operating procedures (called symptom-based procedures) to guide the operators through a process of understanding all the information available from the instrumentation. The new guidance is discussed in detail in Lutz and Williamson (2021c).

Note that a similar loss of feedwater event occurred in 1978 at the Davis-Besse plant, but the operators correctly diagnosed that the RCS had become saturate did not terminate safety injection. This information was never shared with other plant operators, and proposed changes to emergency operating procedures were not finalized (Rogovin and Frampton Jr., 1980; Skillman and Rempe (2021)).

Oconee loss of power

On November 10, 1979, an event occurred at the Oconee Power Station, Unit 3, that resulted in loss of power to a panel that supplied power to the Integrated Control System and the Nonnuclear Instrumentation System. As described in NRC Information Notice 79-29 (NRC, 1979), this loss of power resulted in control system malfunctions and significant loss of information to the control room operator. Although this event resulted in the loss of some instrumentation and control, no significant changes to instrumentation itself were required; it is included here for completeness because it resulted in a loss of instrumentation. The event resulted in investigations into power supplies for instrumentation, as well as guidance for recovery from a loss of instrument power.

Crystal River DC bus failure

On February 26, 1980, an event occurred at Crystal River Unit No. 3 that involved a partial loss of non-nuclear instrument and control power (NRC, 1980e). Although this event resulted in the loss of some instrumentation and control, no significant changes to instrumentation itself were required; it is included here for completeness because it resulted in a loss of instrumentation. The event resulted in investigations into power supplies for instrumentation, as well as guidance for recovery from a loss of instrument power.

World Trade Center attack

Although no nuclear power plants were threatened, the terrorist attack at the World Trade Center in New York City on September 11, 2002 played an important role in enhancing the capabilities of using all available indications from plant instrumentation to determine the plant status and plan a response. Following the World Trade Center attack, the US NRC issued an Order that, in part, resulted in industry developing alternate methods to determine the status of key plant parameters when there is a simultaneous loss of all a.c. and d.c. power distribution in a plant as a result of a terrorist attack (NEI, 2006). Although this did not result in any new instrumentation, it led to the development of guidelines for the use of portable instruments and instruments that do not require electrical power to retrieve key plant parameters (Lutz, 2015).

Fukushima accident

On March 11, 2011, an earthquake followed by a tsunami of great magnitude struck the Fukushima Daiichi nuclear power site in Japan that severely crippled the ability to understand the status of the plants as well as the ability to control plant equipment from the control room (Mizokami and Rempe, 2021). The earthquake severed the main offsite electrical supply to the plant, but the emergency diesel generators responded as designed to maintain critical power to equipment and instrumentation. The following tsunami flooded the diesel generators and eventually, the station batteries, ultimately resulting in a complete loss of both a.c. and d.c. power at Units 1 and 2 while Unit 3 had d.c. power for 20–30 h. Without instrumentation, the operators were “flying blind” as they struggled to maintain control of the plant. After some delay, batteries from the plant were connected to provide power to critical instrumentation.

Incorrect and inadequate instrumentation data compounded the diagnosis of the accident progression. For example, the reference leg of the primary set of the reactor vessel water level instrumentation boiled off resulting in an erroneous indication of reactor vessel level in the normal range while a secondary set of level instrumentation indicated a more realistic very low water level; this is further discussed in “Uncertainty and error” section. The operators were confused by the differences but relied on the primary indication. They had never been exposed to this scenario with disagreeing indications in their training. During the event, there was also

concern (that proved to be unfounded) about fuel overheating and melting in the spent fuel pools caused by boil-off of water as a result of the lack of cooling and makeup to the pools.

Based on insights from the events at Fukushima Daiichi, new instrumentation requirements were ordered to monitor plant conditions. Specifically, the US NRC determined that all power reactor licensees must have a reliable means of remotely monitoring spent fuel pool levels. The NRC issued an order (NRC, 2012) to all licensees requiring wide-range spent fuel pool level instrumentation; the existing spent fuel pool instrumentation could only measure within the normal pool level.

The nuclear industry recognized the importance of instrumentation in preventing an accident caused by external events (e.g., earthquakes and floods) from progressing to a severe accident. As a result, all components of instrumentation (power supplies, cables, sensor, etc.) were reviewed to assure that the power supplies (station batteries and battery chargers) are protected from extreme events and that a diverse means is available to power the battery chargers (NEI, 2016).

The events at Fukushima have also shown that severe accidents can subject electrical and instrumentation and control (I&C) equipment to environmental conditions exceeding the equipment's original design basis assumptions. Severe accident conditions can then cause rapid degradation or damage to various degrees up to complete failure of electrical and I&C equipment. Subsequently, the IEEE issued IEEE Std. 497-2016 (IEEE, 2016), which broadened the scope of the standard to include consideration of the reliability of instrumentation potentially required for coping with severe accidents. In other words, those instruments that would be useful in recovering from a severe accident should provide reliable indication when exposed to severe accident pressure, temperature and radiation conditions. In developing this new standard, the IEEE worked closely with the International Atomic Energy Agency (IAEA) and the US NRC. This resulted in new regulatory requirements (NRC, 2019; IAEA, 2017), similar to the IEEE requirements, for reliable instrumentation that are useful in mitigating a severe accident. While these requirements are only applicable to new plant designs, some existing plants are following the requirements when instrumentation is replaced.

Finally, as a result of the operator performance during the accident related to instrumentation indications, the generic severe accident guidance developed by both the BWR and PWR Owners Groups was updated to include a new Technical Support Guideline (TSG) related to instrumentation performance during a severe accident (Lutz, 2015; Ellison and Williamson, 2015). This is described in more detail in [Application to Procedures and Guidelines](#).

Instrumentation

This section focuses on the various aspects of instrumentation including its classification, treatment of uncertainties and errors, application to procedures and guidance, and measurement of key plant parameters.

Instrument classification

Instruments can be classified by their function and by their quality requirements to ensure the desired level of reliability. The first classification, which is the function, is referred to as "Type" (NRC, 1980c, 2019).

- TYPE A Variables: Those variables that provide the primary information needed to permit the control room operating personnel to take the specified manual actions for which no automatic control is provided and that are required for safety systems to accomplish their safety functions for design basis accident events.
- TYPE B Variables: Those variables that provide information to indicate whether plant safety functions are being accomplished. Plant safety functions are (1) reactivity control, (2) core cooling, (3) maintaining RCS integrity, and (4) maintaining containment integrity (including radioactive effluent control).
- TYPE C Variables: Those variables that provide information to indicate the potential for being breached or the actual breach of barriers to fission product release. The barriers are (1) fuel cladding, (2) primary coolant pressure boundary, and (3) containment.
- TYPE D Variables: Those variables that provide information to indicate the operation of safety systems and other systems important to safety. These variables are to help the operator make appropriate decisions in operation of systems important to mitigating the consequences of an accident.
- TYPE E Variables: Those variables to be monitored as required for use in determining the magnitude of the release of radioactive materials and for continually assessing such releases.
- TYPE F Variables: Those variables that provide primary information to indicate fuel damage and the effects of fuel damage (not applicable to currently operating plants).

Design and qualification criteria for the instrumentation used to measure these variables can be separated into four groups or categories that provide a graded approach to requirements depending on the importance to safety of the measurement of a specific variable.

- Category 1 provides the most stringent requirements and is intended for key variables.
- Category 2 provides less stringent requirements and generally applies to instrumentation designated for indicating system operating status.

- Category 3 is intended to provide requirements that will ensure that high quality off-the-shelf instrumentation is obtained and applies to backup and diagnostic instrumentation.
- Category 4 is intended to provide requirements for measurement of key variables when the plants conditions (e.g., pressure, temperature and radiation) are beyond design basis conditions.

A key variable is that single variable (or minimum number of variables) that most directly indicates the accomplishment of a safety function (in the case of Types B and C), the operation of a safety system (in the case of Type D), or radioactive material release (in the case of Type E). It is essential that key variables be qualified to the more stringent design and qualification criteria. The design and qualification criteria category assigned to each variable indicate whether the variable is considered to be a key variable for system status indication or for backup or diagnosis, i.e., for Types B and C. Key variables are Category 1; backup variables are generally Category 3. For Types D and E, the key variables are generally Category 2; backup variables are Category 3.

Category 1 instrumentation has the following design and qualification requirements:

- The instrumentation should be qualified through testing to be reliable in the environmental conditions that would exist for a design basis accident, including seismic effects; see for example (NRC, 1984).
- The instrumentation should have redundancy in indications and power supplies such that no single failure would prevent plant operators from being presented with the information.
- The instrumentation should be powered from standby power sources and should be backed up by batteries.
- The instrumentation should have continuous readout and at least one channel should be recorded; the frequency of parameter sampling for display and recording is not specified in NRC (1980c).
- The instrumentation should be maintained and calibrated on a periodic basis.
- The instrumentation should receive inputs from sensors that directly measure the desired variables, to the extent possible.

Examples for BWR and PWR instrumentation in each of the types is provided in Table 1.

Uncertainty and error

Errors in instrumentation readouts can be attributed to calibration errors, instrument failure errors, known instrument errors, and errors induced by environmental conditions. Calibration errors are typically small, and procedures are designed to ensure that the same calibration errors are not made on multiple channels of instruments reading the same variable. Multiple channels of an instrument are designed to ensure that errors caused by instrument failure are detectable (e.g., one of four channels reading very different from the other three).

Table 1 Example BWR and PWR variables for each type (not all inclusive).

Type	Example BWR variable	Example PWR variable
A	Drywell Pressure	Steam Generator Water Level
B	Neutron Flux	Neutron Flux
	Reactor Vessel Coolant Level	Pressurizer Water Level
	Reactor Vessel Pressure	Core Temperature ^a
		RCS Pressure
C		Containment Pressure
	Radiation Level in Circulating Coolant	Radiation Level in Circulating Coolant
	Primary Containment Radiation	Containment Radiation
	Suppression Pool Water Level	Refueling Tank Water Level
D	Drywell Oxygen and Hydrogen Level	Containment Hydrogen Level
	Main Feedwater Flow	Main Feedwater Flow
	Condensate Storage Tank Level	Condensate Storage Tank Water Level
	Emergency Core Cooling System Flows	Containment Spray Flow
E	Containment Temperature	Containment Temperature
	Safety Injection Flows	Safety Injection Flows
	Area Radiation	Area Radiation
	Radiation in Exhaust Lines	Radiation in Exhaust Lines
F	Vent Flow Rates	Vent Flow Rates
	Meteorological Conditions	Meteorological Conditions
	Core Temperature ^a	Core Temperature ^a
	Reactor Vessel Pressure	RCS Pressure
	Drywell Pressure	Containment Pressure
	Drywell Temperature	Containment Temperature

^aThere is no direct indication of "Core Temperature"; it must be inferred from other parameters such as core exit thermocouples, reactor coolant superheat, etc.

Every instrument has a known error band (e.g., plus or minus 1%). This error is usually referenced to the maximum range of the instrument. Therefore, a 1% error on reactor vessel pressure [which has a maximum range of 1500 psig (10.34 MPa-g)] would be 15 psig (0.1 MPa-g). This is quite acceptable in the normal operating range of 1200 psig (8.27 MPa-g) but could be quite large at the lower end of the range (e.g., 20 psig/0.137 MPa-g), where the error could be nearly as large as the measured value. This likely only to occur when the instrument readout is used as a Type F variable to determine if the reactor vessel and drywell pressures are equalized. An example is the use of a narrow-range instrument when making a comparison between reactor pressure vessel (RPV) pressure and drywell pressure.

The final error is that induced by environmental conditions. The most likely instrument to be subject to this is level instrumentation for components inside the primary containment or drywell. Level instruments typically compare the weight of a column of water in a vessel to a known pressure that is near atmospheric pressure. A reference leg inside the primary containment is used for this comparison. If the pressure in the primary containment is high during an accident, the reference leg used for comparison would result in a bias in the instrument readout. Correction factors for environment conditions within the design basis are pre-calculated for steam generator level (PWRs) and reactor vessel level (BWRs).

An extreme case occurred in all three of the units that were operating at Fukushima Daiichi on March 11, 2011 (see [Mizokami and Rempe, 2021](#)). As shown in [Fig. 1](#), when water in the reference leg for the reactor vessel level instrumentation boiled-off due to high temperatures in the drywell (i.e., primary containment); instrumentation (i.e., a water level gauge using a differential pressure, dP, cell) will indicate that water is above the top of the core when in fact, the water level is below the top of the core.

Application to procedures and guidelines

Instrument errors need to be addressed in Emergency Procedures and Guidelines. For normal instrument error, the setpoints for operator action are adjusted for the maximum expected error in PWRs. For BWRs, the as-is indication (corrected for any off-calibration) is used for operator actions because it is not possible to identify the conservative bias in all cases.

For errors caused by environmental conditions in PWR emergency procedures, two setpoint values (directing operator actions) for steam generator level are provided—one for low containment pressure and another for high containment pressure (called adverse conditions).

For severe accident guidelines, special Technical Support Guidelines ([Lutz, 2015](#); [Ellison and Williamson, 2015](#)) were developed to assist the emergency response staff for several reasons:

- If the plant conditions are beyond the design basis and instrumentation qualification envelope, the instrument reliability could be impacted,
- The instrument response to some operator actions during a severe accident may be outside the expected instrument response for design basis accidents,
- The instrument response during a severe accident may provide some diagnostic assistance to the emergency response staff if the expected response to various actions are identified,
- The indications from the primary set of instrumentation for most key plant parameters can be validated using a diverse set of instrumentation, including the use of computational aids to translate unrelated parameters to the key parameter.
- Alternate means of obtaining most parameter values are available if power to instrumentation is unavailable ([Lutz et al., 2016](#)).

Measurement of key plant parameters

This section provides examples of instrumentation used to measure key plant parameters in a nuclear power plant. More detailed information is provided in Hashimian (2014) and Upadhyaya and Wood (2020).

- Water Temperatures: Water temperature is typically measured by either thermocouples (TCs) or resistance temperature detectors (RTDs). The choice depends on the expected temperature range of the water.
 - RTD sensors are thin film or wire wound resistor elements that use the ohm resistance value to indicate a temperature value. The resistance simultaneously increases with temperature increase and vice versa. RTDs are typically used for measuring water temperature when the range is less than about 700 °F (370 °C).
 - TC sensors consist of two dissimilar metal wires joined at a hot junction. As temperature changes, a millivolt signal is generated. The most common alloy combinations used in PWRs and BWRs are known as Type J for applications less than about 1500 °F (800 °C) and Type K for applications less than about 2000 °F (1100 °C). They are typically used for temperature measurements requiring faster response times.
- Pressure: Liquid or gas pressure is typically measured with either an elastic element gauge such as a bellows or diaphragm, or electrical transducers such as strain gauges.
- Water Level: Liquid water levels are typically measured by a differential pressure (dP) cell. As discussed in “Uncertainty and error” section (see Fig. 1), a dP cell measures the difference in pressure between the bottom of the column of water and the pressure of a column of water in a “reference leg” that is exposed to a known pressure. Adjustments for temperature of the measured fluid and that of the water column in the reference leg are needed for an accurate measurement if temperatures are expected to vary significantly.
- Neutron Flux: Neutron flux is typically measured using three separate instruments with varying shielding because the range of energy of thermal neutrons that can cover eight order of magnitude. Source range, intermediate range and power range neutron detectors are normally used in PWRs and BWRs with the source range used to detect subcriticality, the intermediate range is used during startup and shutdown and the power range is used during normal operation.
- Hydrogen: Advances in hydrogen measurement results in two different detector methods in use today. The older method, which draws a sample of gas containing air, steam and hydrogen, splits the sample and burns all hydrogen in the first sample. The difference in electrical conductivity of the two samples is a measure of the hydrogen concentration because hydrogen molecules have a significantly different conductivity compared to air. The newer method measures the temperature of a hydrogen passive recombiner surface. That temperature is correlated to the hydrogen concentration because higher hydrogen concentrations have more rapid recombination.
- Radiation: The most common radiation measurement is for gamma radiation. The ionizing effect of radiation is measured using various methods including scintillation detector, ionization chamber and gamma counter (Han, 2000).
- Flow Rates: Flow rates are most commonly measured by determining the pressure drop through an orifice or nozzle using common pressure measurement devices.

Control (protection) function

This section focuses on the safety related control function of instrumentation. Control systems are designed to maintain the reactor within operational limits during power operation of the plant. For example, a control system monitors the water level in the steam generators of a PWR and adjusts the incoming feedwater flow to maintain that level within prescribed limits. These limits are well below the safety limits to ensure safety during operational disturbances, including accidents. Another part of the plant control system is designed to shut the reactor down, keep it shut down and ensure core and system cooling as well as prevention of radioactivity releases if plant parameters exceed certain plant safety limits.

The safety related control systems used to maintain plant systems within acceptable bounds in the event of an off normal event or accident event can be classified as those having either an automatic control function or a control function initiated by the plant operators. The automatic control functions are typically the RPS actuation or the ESF actuation. These are controls that are needed to be actuated quickly to protect the core and prevent radioactivity releases. Control functions initiated by the plant operators during an accident are generally those to terminate operation of safety systems or to perform longer term actions following ESF actuation. In addition, all of the ESF systems can be manually actuated by the plant operators as instructed in the plant EOPs. There are also a limited number of operator initiated control actions for which no automatic actions are available. The instrumentation to guide the operators for these actions are classified as Type A instrumentation (see section Instrumentation Classification). Examples of PWR and BWR control functions for off-normal and accident conditions are provided in Table 2.

As a measure of defense in depth, safety limits for RPS (see Lutz and Williamson, 2021a) actuation are set below calculated allowable limits to ensure that any unanticipated delays in protection system response will not cause unacceptable consequences. The setpoints for ESF (see Lutz and Williamson, 2021b) actuation are chosen based on safety analyses to prevent damage to the reactor core and to prevent the release of radioactivity to the environment. The introduction of digital systems in place of analog systems in some areas of the protection systems has been done as analog systems become obsolete. The improved reliability of digital systems, simplified surveillance testing and reduced duration of plant shutdown for testing are also benefits of the digital systems.

Table 2 Example control systems required for emergency conditions.

Function	PWR	BWR
RPS	Reactor Trip	Reactor Trip
	ATWS Trips	ATWS Trips, Alternate Rod Insertion
ESF	Safety Injection Initiation	Core Spray Initiation, Low- and High-Pressure Coolant Injection Initiation, Automatic Depressurization Initiation
	Containment Spray Initiation	
	Containment Isolation	Primary Containment Isolation including Reactor Water Cleanup Isolation Initiation
	Steam Line Isolation	Main Steam Line Isolation
	Turbine Trip and Feedwater Isolation	Turbine Trip
	Auxiliary Feedwater Initiation	Reactor Core Isolation Cooling Initiation
		HPCI Isolation Initiation, RCIC Isolation Initiation
	Safety Injection Automatic Switchover to Containment Sump	HPCI Auto Switchover from Condensate Storage Tank to Suppression Pool
Post-Accident Manual Control	ESFAS Interlocks	
	RCS Boration to Shutdown	Manually initiate Standby Liquid Control (SLC) and Alternate Rod Insertion (ATWS)
	Safety Injection Termination	Control Safety Injection and RCIC Termination
	Steam Generator Level Control with Auxiliary Feedwater	Initiate Containment Sprays and Suppression Pool Cooling
	Defeat Containment Isolation	Initiate Containment Inerting

Control systems typically rely on inputs from several independent monitors of a particular plant parameter, called instrument channels. In some cases, input for more than one plant parameter is needed for actuation (i.e., coincident signals). These inputs are then “auctioneered” to ensure that a single erroneous input (e.g., from a failed instrument) does not result in actuation of the control function. For example, PWR reactor trip actuation requires a low steam generator water level input from two-out-of-four instrument channels from any single steam generator. Power supplies for the control function are subject to the same requirements as those for the instrumentation providing input to the control system.

Summary

Reliable and accurate instrument is key to safe operations of a nuclear power plant. Instrumentation connects the plant operations staff to the plant conditions by providing feedback regarding the value of key plant parameters. The term instrumentation includes the sensors which measure a plant parameter and convert that measurement to a signal (voltage, resistance, amperage); cables that carry the signal, transmitters that amplify the signal; processors that convert the signal into a useful indication; displays (meters or readouts) that allow the plant operations staff to observe (and take actions); and recorders that preserve the information for further use.

Nuclear power plant instrumentation has been enhanced over time to provide plant operators and emergency responders with more reliable means to understand the plant conditions during an event. Lessons learned from instrumentation issues during plant events (including but not limited to the TMI-2 and Fukushima accidents) have been considered to improve instrument reliability as well as development of guidance for plant operators for interpreting instrumentation feedback.

Control systems are designed to maintain the reactor within operational limits during power operation of the plant. These limits are well below the safety limits to ensure safety during operational disturbances, including accidents. Another part of the plant control system is designed to shut the reactor down, keep it shut down and ensure core and system cooling, as well as prevention of radioactivity releases, if plant parameters exceed certain plant safety limits. Control systems used to maintain plant systems within acceptable bounds in the event of an off normal event or accident event can be classified as those having either an automatic control function or a control function initiated by the plant operators. The automatic control functions are typically the RPS actuation or the ESF actuation. Control functions initiated by the plant operators during an accident are generally those to terminate operation of safety systems or to perform longer term actions following ESF actuation. These control systems are subject to the same redundancy, diversity, separation and fail-safe requirements as the instrumentation that provide input to the control systems.

Glossary

ATWS Anticipated Transient Without Scram.

BWR Boiling Water Reactor.

Emergency Operating Procedure A set of instructions that are to be implemented following an unintentional reactor trip or safety injection initiation.

Guidance Any set of instructions that are *recommended* to be implemented under prescribed plant conditions.

Procedures A set of instructions that are *required* to be implemented verbatim under prescribed plant conditions.

PWR Pressurized Water Reactor.

Owners Group A group of plant owners with similar plant designs (usually by reactor vendor or reactor type) that fund development programs common to their plant designs.

Special Events Upset conditions or accidents whose safety analysis may not be part of the plant design basis but are approved by the regulator as part of plant licensing in the United States (e.g., Station Blackouts (SBO) and Anticipated Transients Without Scram (ATWS)).

Introduction

Procedures and guidance have always been a part of the operation of nuclear power stations to assure that the plant operation remains within regulatory limits and to protect the plant operator's investment in the facility. The earliest procedures and guidance were focused on operation of the plant as well as responding to likely events that could disrupt normal operation. The procedures were based on recognizing an event and following procedures to respond. The set of events for which procedures were developed were a limited set of design basis events and did not include possible deviations in the event progression. There was no process for incorporation of lesson learned from operating events into the operator procedures. As a result, there was little sharing of knowledge amongst the operating plants.

A significant change came about as a result of the accident at Three Mile Island Unit 2 (TMI-2) in 1979. As emphasized in [Skillman and Rempe \(2021\)](#), investigations into the causes of the accident ([Rogavin et al., 1979](#)) highlighted weaknesses in the plant operating and emergency procedures and guidance, as well as training, in several areas:

- Poor operator procedures that offered no useful assistance,
- A lack of diagnostic skill because operators had never been trained to understand plant parameters,
- Confusion caused by misleading or erroneous instrumentation.

In addition, the investigation by the Kemeny Commission ([Kemeny et al., 1980](#)), which President Carter formed to investigate the accident at the TMI-2 nuclear power plant, recommended the following:

- The (nuclear power) industry should establish a program that specifies appropriate safety standards including those for management, quality assurance, and operating procedures and practices, and that conducts independent evaluations.

- There must be a systematic gathering, review and analysis of operating experience at all nuclear power plants, coupled with an industry wide international communications network to facilitate the speedy flow of this information to affected parties.

This resulted in three significant events that transformed procedures and guidance from the pre-TMI era to today:

- The U.S. Nuclear Regulatory Commission (NRC) upgraded regulatory requirements in the area of emergency procedures and training (NRC, 1980, 1982). Most significant was the requirement for development of symptom-based emergency procedures.
- The nuclear power industry established the Institute of Nuclear Power Operations (INPO), as an autonomous organization to promote the highest levels of safety and reliability in the operation of commercial nuclear power plants. INPO has been particularly responsible for excellence in training as well as a systematic gathering, review and analysis of operating experience at all nuclear power plants, coupled with an industry wide international communications network to facilitate the speedy flow of this information to affected parties.
- The nuclear power created Owners Groups to facilitate the development and maintenance of symptom-based emergency operating procedures that fulfill the new regulatory requirements. A separate Owners Group was created for each American reactor vendor design (Westinghouse, General Electric, Combustion Engineering and Babcock & Wilcox). The Owners Groups were controlled by the plant operators for each reactor vendor design and provided a common source of funding for the development and maintenance of a set of generic symptom-based emergency procedures that could easily be implemented by each reactor operator.

As a point of clarification, at some point after the year 2000, the three Owners Groups from the PWR reactor vendors were combined to form the PWR Owners Group. However, some products of the previous Owners Groups, such as generic Emergency Operating Procedures, are still maintained and updated in their original content and format. It is also noted that in addition to the four Owners Groups in the United States, other Owners Groups were also established (e.g., Framatome/AREVA plants, Canadian CANDU plants and the Nordic BWR plants).

While much of these efforts were aimed at emergency procedures, the fruits of these labors led to similar improvements in all other procedures and guidance, including training.

Plant conditions

The IAEA Safety Glossary (IAEA, 2018) defines five plant states as shown in Fig. 1. These plant states indicate the degree of safety threat associated with that state, ranging from operation states to accident conditions. The three left-most states constitute operation within the plant design basis. The right-most two states constitute design extension conditions. This chapter focuses on the guidance provided for the plant staff when the plant state is within its design basis. Lutz and Williamson (2021) focuses on the guidance provided for design extension conditions (also sometimes called guidance for beyond design basis conditions).

Regulatory guidance (IAEA, 2004; NRC, 2017) specifies that procedures and guidance shall be developed and used by the operating organization to ensure the safe management of the plant. The processes to develop, approve, revise and implement plant procedures should be described in the Safety Analysis Report. A list of the main plant administrative procedures used to control the plant procedures should be also provided.

The “plant design basis” is defined in the IAEA Safety Glossary as the range of conditions and events taken explicitly into account in the design of structures, systems and components and equipment of a facility, according to established criteria, such that the facility can withstand them without exceeding authorized limits. Therefore, guidance for design basis conditions would refer to

Fig. 1 Five plant states identified by IAEA. Courtesy of IAEA (2018) *IAEA Safety Glossary: Terminology Used In Nuclear Safety and Radiation Protection, 2018 Revision*, International Atomic Energy Agency.

that set of guidelines and procedures that are used when the plant state is either in Normal Operation, Anticipated Operational Occurrences, or Design Basis Accidents.

Several points of clarification, based on acceptable practices in the United States and Europe, are needed here. These are also consistent with regulatory requirements of the IAEA (IAEA, 2016).

- In the United States, there is a difference in terminology between “design basis” and “current licensing basis”. In Europe there is a 10-year periodic review where the plant design basis is updated per regulatory requirements before permission to operate for another 10 years is given. However, because there is no “periodic review” of the plant design basis in the United States, the “design basis” is set at the time of initial licensing of the plant. The “current licensing basis” includes the collection of documents or technical criteria that provides the basis upon which the NRC issues a license and subsequent enhancements to satisfy new regulatory requirements after initial licensing. For simplicity in this chapter, design basis accidents are all of those studied as part of the design basis as well as the licensing basis of a plant.
- Guidance is generally referred to as a set of instructions that are recommended to be implemented under prescribed plant conditions. Procedures are generally referred to as a set of instructions that are to be implemented verbatim under prescribed plant conditions.
- The format and content of guidelines and procedures can vary, as long as they follow human factors principles. Current guidelines and procedures can be arranged as step-wise text, flow diagrams, logic diagrams, etc. Guidelines and procedures are typically thought of in terms of printed paper copies but recently they have begun to be written as electronic media that can be used interactively.
- Plant administrative procedures, while not covered in this chapter, control the development, updating, training and usage of plant guidelines and procedures. These aspects are just as important as the content of the guidelines and procedures themselves because they ensure the quality and consistency of the guidelines and procedures.
- The development of guidelines and procedures should include both verification and validation phases. Verification refers to the process used to ensure that the instructions are appropriate (i.e., technically accurate for their prescribed plant conditions). This is typically done using simulation tools, including the full-scale plant training simulator. Validation refers to the process used to ensure that the instructions can be executed properly (i.e., clearly written and understood) by the appropriate plant staff. This is typically done by presenting a simulated event to the end-user and observing that user’s activities.

Operational states

Operational States shown in Fig. 1 are those plant states wherein continued operation of the plant is permitted based on meeting all regulatory requirements. In the case of anticipated operational occurrences, the plant technical specifications may limit the time that the plant can remain in operation if the plant cannot be returned to normal operating conditions.

Normal operation

Procedures and guidance for the first “Operational State” are for “normal” operation of the plant and typically have two purposes. First and foremost, procedures and guidance ensure that plant operation meets all regulatory requirements for safe operation. Those regulatory requirements for safe operation are contained in the plant “Technical Specifications.” Secondly, procedures and guidance ensure that the plant and all its components are operated in an efficient manner to maximize plant output. Procedures (as opposed to guidance) are typically provided that require the user to execute each step as written.

There are many procedures for normal operation, including:

- System Operating Procedures that provide instructions for operation of each plant system,
- Start-up Procedures that provide instructions for start-up of the plant to full power operation,
- Shutdown Procedures that provide instructions for shutdown of the plant from full power operation to other operating modes such as Hot Standby, Hot Shutdown, Cold Shutdown and Refueling. The operating modes for light water reactors in the United States are defined in their plant Technical Specifications as shown in (NRC, 2012a,b,c,d,e),
- General Operating Procedures that provide instructions for safe operation of the plant when at full or partial power,
- Maintenance Procedures that provide instructions for routine maintenance of plant components as well as repairs for faulted components,
- Instrument Calibration Procedures that provide instructions for ensuring that instrumentation is accurate and within its design basis, and
- Surveillance Procedures that provide instructions for inspection of plant components on a regular basis.

These procedures are used by various staff members as prescribed in the plant administrative procedures (see later for qualifications of staff members including training). For example, the plant Operating Procedures, Start-up Procedures and Shutdown Procedures are typically only used by licensed plant operators. System Operating Procedures may be used by Auxiliary Operators. The remainder of the above listed procedures would be used by specialists in specific disciplines.

Anticipated operational occurrences

Procedures and guidance for the second “Operational State” address “Anticipated Operational Occurrences” and provide instruction for responding to system anomalies for which regulatory requirements allow the plant to remain operational. Again, these are typically developed as procedures wherein the user must execute each step without deviation. The use of these procedures is to return the plant to a “normal” operating state and prevent the plant from entering a state that exceeds regulatory requirements.

There are many procedures in this plant state, including:

- Alarm Response Procedures that provide instructions for responding to plant parameters that are beyond the expected range of values as indicated on the plant control room alarm board,
- Abnormal Operating Procedures that provide instructions for responding to plant events that do not cause the plant to exceed its design basis. These are sometimes called Off-Normal Operating Procedures. Examples of these procedures range from response to the loss of a redundant train of a plant system, response to fires, or response to excessive temperatures in a system of component.

Design basis accidents

The design basis accident state consists of procedures for events that initiate a reactor trip signal and/or a safety injection signal (to start emergency core cooling water flow). These procedures, generally called Emergency Operating Procedures (EOPs), have the singular purpose of returning the plant to a safety stable state that may either be a shutdown condition or a return to power operation. These are typically procedures (as opposed to guidance) wherein the user must execute the procedure steps as written.

Prior to the accident at TMI-2, the EOPs were a series of procedures for each design basis accident that is analysed in the plant Safety Analysis Report. These are referred to as event-based procedures because the user was required to diagnose the event and then start in the correct procedure. As discussed in [Skillman and Rempe \(2021\)](#), an important lesson learned from the TMI-2 accident ([NRC, 1980, 1982](#)) is that EOPs need to be made symptom-based rather than event-based so that the user can respond to indications on the main control board (instrumentation as well as indication of valve positions).

To provide a cost-effective means to address the guidance in [NRC \(1980\)](#), each of the four reactor vendors in the United States (Westinghouse, Combustion Engineering, Babcock and Wilcox, and General Electric) formed an “Owners Group” to develop symptom-based EOPs for staff to operate their reactors. For the most part, the reactor vendor provided technical support to the Owners Group while plant staff provided input from a plant operation perspective. Owing to differences in plant design within each reactor vendor’s Owners Group, these new emergency procedures were developed as generic guidelines that would be applicable to all plants within the Owners Group but did not include specifics of any plant design that were not common to all designs (e.g., system components, instrumentation, etc.). These generic guidelines included those symptoms that should cause a user response as well as the appropriate response. The individual plants would then be expected to provide plant specific information related to symptoms and responses (e.g., instrument readings that should cause a response and the equipment that should be manipulated as a result). International plant owners for each reactor vendor were also invited to become members of the appropriate Owners Groups.

In addition to being symptom-based, the EOPs covered all design basis accidents and Special Events, as required by the NRC. These symptom-based procedures also included instruction on recovery steps if one or more pieces of design basis equipment was unavailable (e.g., out-of-service at the time of the event or fail to start or run). For the first time, the new procedures also incorporated results from generic probabilistic risk assessment (PRA) studies such as WASH-1400 ([NRC, 1976](#)).

Because the generic EOPs were developed by each Owners Group with little or no interaction with each other, the format of the resulting generic procedures was significantly different. However, the content of the generic procedures was quite similar because all of the generic procedures were reviewed and approved by the U.S. NRC. Note although the three Owners Groups for the American PWRs were combined, vendor specific EOPs remain for each of the three PWR reactor vendors. This is primarily due to the enormous costs for retraining plant operating staff for entirely new procedure sets.

Scope of generic emergency operating procedures

The EOPs were designed for use by the control room operators, including shift supervisors and station technical advisors (STA), which were recommended in the United States by the NRC ([NRC, 1980](#)). Features of the EOPs for all plants in the United States and western Europe include:

- Entered upon reactor trip or safety injection signal
- Entry procedure has two purposes: ensure appropriate safety equipment has automatically actuated and diagnosis of accident ‘type’ based on symptoms as read from the main control board
- Procedures pass from one to the next – PWR operators rely on one procedure at a time; BWR operators can be using several EOP flow charts simultaneously based upon the reactor pressure vessel (RPV) and containment control parameter indications.
- Procedures include checking symptoms related to Critical Safety Functions (reactivity, core cooling, heat sink, inventory, pressure and containment) and response procedures when one or more symptoms are out of their acceptable range.

The content of the EOPs for each reactor vendor’s Owners Group are somewhat different in terms of breadth (range of events specifically covered) and depth (degree of reliance on knowledge, skills and abilities) of the procedures. The development of the initial

EOPs by the Owners Groups, as well as subsequent enhancements, was controlled by a group of experts from plant operators and consultants with experience in operations and accident analysis. As a result, each of the four Owners Groups addressed issues differently (this separation continued after the consolidation of the PWR Owners Groups).

The scope of the EOPs, in terms of the accident sequences addressed, is much enhanced from the rigorous definition of design basis accidents and special events. Design basis accidents typically include: the definition of an initiating event; a worst-case single failure (NRC, 1979); and an event mitigation required to achieve a safe stable state. For all credible initiating events, the EOPs first provide guidance for the operating staff to verify that automatic actions have successfully initiated, and safety systems are performing their functions. In the event that one or more safety systems or components fail to initiate or perform their required functions, the EOPs provide guidance to restore the “failed” function. Two important points are worth noting:

- The EOPs verify that all redundant safety systems and components are initiated and operating as intended even though only a single subsystem or component is required for successful mitigation.
- For Westinghouse PWRs, the scope of the EOPs is based on probabilistic safety analyses (see Fleming, 2021) to determine credible failures that should be addressed. A frequency of about once in 1 million years (i.e., 1E-06 per year) was typically used for EOP development. Event sequences (i.e., initiating event combined with equipment failures) whose predicted frequency of occurrence are less than 1E-06 per year are typically excluded from EOPs in order to focus operator training on the more likely events. Thus, the EOPs address a spectrum of conditions including those more severe, as well as those less severe, than were considered in developing the plant design basis, including multiple equipment failures and operator errors.
- BWRs have attempted to identify any mechanistically possible plant conditions for which generic operational guidance can be provided and address them in the generic emergency procedures to minimize the impact on public health and safety, irrespective of the probability of occurrence. Similar to the Westinghouse PWRs, the EOPs address a spectrum of conditions including those more severe as well as those less severe than were considered in developing the plant design basis, including multiple equipment failures and operator errors.
- The frequency of an accident initiated by a catastrophic failure of the reactor vessel is typically estimated to be once in 1 million to once in 10 million years (NRC, 1976) and is therefore not specifically addressed in the EOPs because there are no possible recovery actions; this event was assumed to lead directly to core damage and a severe accident.

A detailed description of the EOP structure for the Westinghouse PWRs, General Electric BWRs, Siemens PWRs (Germany), Electricite de France PWRs, CANDU (Canadian Pressurized Heavy Water Reactors) and Combustion Engineering PWRs is provided in Appendix II of IAEA Safety Report Series No. 48 (IAEA, 2006).

Format of generic emergency operating procedures

For the same reasons that the content of the generic EOPs developed by each Owners Group is somewhat different, the format of the generic EOPs for each Owners Group is quite different.

All of the Owners Groups for the PWRs developed stepwise generic procedures wherein the user would execute a specific step and then move to the next step in the procedures.

- The Westinghouse Owners Group developed their generic EOPs in a two-column format where the left-hand column contains a setpoint for a symptom and the instruction(s) if the setpoint is satisfied; this is called the expected response. The right-hand column contains instruction(s) if the setpoint is not satisfied; this is called Response Not Obtained. For example, the left-hand column may state “At least one Safety Injection pump running” with an instruction to go to the next step if that is satisfied; if it is not satisfied, the right-hand column may state “Start at least one Safety Injection Pump”.
- Other PWR Owners Groups developed their generic EOPs in a one-column format where the instructions are provided for both cases (satisfies the setpoint for the symptom and does not satisfy the setpoint).

The BWR Owner’s Group developed their generic EOPs as a guideline addressing the different radiation barriers: RPV control, Primary Containment Control, Secondary Containment Control and Offgas and Radiation Release Control. Each guideline addresses one of the barriers for release of radiation. Within each guideline, monitor and control of important parameters, such as RPV water level and reactor pressure, is accomplished by implementing a series of actions to return the barriers to their Technical Specification conditions. Within each guideline, provision is made for additional actions if the previous action was not effective or was not available. Originally BWR utilities tried to implement these guidelines as text-based EOPs. However, plant owners began to develop flowcharts to implement the actions in place of text-based guidelines.

As a result, the BWR Owners Group generic EOPs now consist of a series of flow charts based on controlling parameters in the RPV, the primary containment, the secondary containment and offsite radioactive release and restoring those parameters to preferred operating band. Within each flow chart are decision boxes depending on whether a setpoint value was satisfied and then high-level steps that can be taken. The flow charts are backed-up by more detailed procedures for responding to a critical safety function that is beyond its setpoint. The BWROG generic EOPs are referred to as “strategic,” which work to restore the plant to the preferred operating band. In turn, they call upon text-based support procedures for tactical actions, such as starting a pump or using a means to control RPV pressure.

Procedure implementation

Implementation of the generic Owners Group procedures at a nuclear generating station is a multi-step process that includes development of plant specific procedures; verification and validation; training; and qualification. Implementation also includes site specific interface issues such as procedure usage; command and control; interface with the Technical Support Center (TSC); and emergency planning. Each of these is discussed below.

- Plant Specific EOPs – The first step in implementing the generic Owners Group EOPs (or any significant revision to them) is converting the generic procedures to plant specific procedures. The generic EOPs were developed based on a reference plant design that includes most of the applicable features (e.g., equipment, layout, etc.) of the plants in each Owners Group. Therefore, each plant may have features that deviate from the reference plant for which plant specific instructions need to be developed.

There are several major steps involved in the conversion including: development of plant specific setpoint values (control room indications that might require response actions); replacement of generic equipment names with plant specific equivalent equipment; and addition or deletion of instructions based on plant specific equipment. There are also format issues to ensure that the plant specific EOPs fit into the overall procedure schemes, such as numbering systems and denoting “continuous action” steps.

- Verification and Validation (V&V) – The generic EOPs are verified and validated by the Owners Group before they are distributed to member plant owners. This provides a level of assurance that the EOPs are technically accurate and procedures are clear and easy to use. As a result, the plant operator only needs to verify that the plant specific EOPs are a technically correct implementation of the generic material or prepare supporting justification for deviations. Each plant operator then validates the plant specific EOPs with one or more of their operating crews, typically using the plant full-scope simulator, by exercising each procedure pathway that has changed.
- Procedure Usage – The final phase of EOP development and implementation deals with usage. This refers to specific roles and responsibilities of the persons in the plant control room as well as interfaces with other plant emergency personnel. It also includes communication amongst three licensed operators within the control room while using the procedures (i.e., 3-way communication). Typically, one licensed control room operator would be responsible for reading the EOPs and making callouts for various symptoms and equipment status. A second licensed operator would be at the control board(s) reading instrumentation and equipment status information displayed on the control board; this task could be with another licensed operator when staffing permits. A third licensed operator would be responsible for monitoring the event progression and checking critical safety functions to assure that the appropriate procedures and actions are being taken. All communication in the control room in the United States uses three-way communication (INPO, 2006) wherein the receiver of a command or request will repeat back the command or request and then the originator will verbally confirm that the receiver correctly understands the command or request. While this can slow progress through multi-step procedures, it has been shown to be effective in preventing errors caused by various communication issues.

There are a few exceptions to the three-way communication requirement for certain fast-moving events such as anticipated transient without scram (ATWS). For example, once the failure of the control rods to insert is confirmed when a scram signal is present (i.e., an ATWS), the plant operators can take certain actions that do not involve any decision making. When they finish, the actions are reported to the plant supervisor. At this point, the three-way communication is resumed.

- Training – Training for use of the plant specific EOPs should follow the appropriate guidance (IAEA, 1996; INPO, 1993). This training process is called Systems (or Systematic Approach to Training (SAT). SAT is organized into distinct phases of Analysis, Design, Development, Implementation, and Evaluation, and relies on Feedback as a process for continuous improvement. Analysis refers to analysing training to determine the knowledge, skills and abilities that each job requires. Design refers to strategies for training course design including key learning points trainees must grasp. Development refers to the actual development of training modules (self-study, classroom, etc.). Implementing training refers to putting the training into practice. Evaluation refers to the assessment of trainee’s ability to use the procedures and includes feedback for enhancement of the procedures.
- Certification (Qualification) – Following the completion of training nuclear plant operators must undergo a strenuous test of their ability to properly use the EOPs during simulated scenarios that include routine operation, abnormal occurrences, and accidents. In the United States, there are two levels of certification: reactor operator and senior reactor operator; the latter requires more extensive experience as a reactor operator.
- Command and Control – As part of the required planning for responses to emergency conditions (as specified in the plant Emergency Plan), each licensee has established a command and control structure for their Emergency Response Organization (ERO). Within this structure, there are position(s) with the assigned authority and responsibility for providing overall direction on the implementation of EOPs (as well as other procedures and guidance). Typically, the Shift Manager is the licensed person in the control room who has ultimate responsibility for the actions taken in the control room.
- Emergency Planning – Each plant has an Emergency Plan that specifies certain interfaces between the EOP user and other organizations that need to be aware of the plant conditions when the EOPs are in use. Some of these include the regulatory agency, local law enforcement and emergency medical service organizations, and any civil defense organizations. In the United States, there are Emergency Action Levels (NEI, 2012) that prescribe the interfaces based on plant conditions during the use of the EOPs. The EOP user needs to understand the requirements to provide timely notification of plant conditions to organizations outside of the nuclear station.

Procedure review and updating

The Generic EOPs are maintained by each Owners Group. Each Owners Group has a dedicated group of individuals that have operations and analysis expertise to maintain these generic EOPs to state-of-the-art standards. These groups review feedback from EOP users, new research on equipment behavior under transient events or accidents, and new regulatory requirements.

Because the EOPs are exercised regularly by plant operations staff during training drills, exercises as well as certification exercises, they are frequently used for a wide range of scenarios by a wide range of personnel. Any question that arises during these training and certification scenarios, as well as during an actual transient or accident, are referred to the Owners Group for resolution. Feedback from the plant operator experts and consultants regarding new research findings, including new regulatory requirements for new events, such as containment recirculation sump blockage (NRC, 2002), are also referred to these groups, which determine the safety importance of each feedback item and prioritize investigations leading to resolution. If the dedicated group determines that a change to the generic EOPs is recommended, the Owners Group will issue a revision to the generic EOPs (typically only the revised step(s) and not the entire EOP set).

Once the Owners Group issues a revision to the generic EOPs, it becomes incumbent upon each plant to update their plant specific EOPs in a *timely manner*. The term *timely manner* needs to be clarified because the change in plant specific EOPs is a multi-step process. Therefore, timely is interpreted based on safety significance and may vary from a few months to a year or more. The multi-step process involves drafting the change to the plant specific procedure, performing V&V (see earlier discussion of V&V) on the change, making changes to training materials and ensuring that the trainers are well versed in the change, and training the certified operators on the new procedure step(s). Only then will the new procedure step(s) be included in the EOPs in the plant control room. Typically, any EOP changes are introduced into the plant licensed operator training cycle which may extend over a five- or six-week period.

Summary

Procedures and guidance are key to the safe and efficient operation of nuclear power stations. Every activity that is carried out in a nuclear power station is controlled by procedures and guidance that are expected to be followed. This ranges from plant operation and maintenance activities to accident emergency response activities. These procedures and guidance assure a consistent approach for each activity, allowing it to be carried out safely and avoiding any errors.

The approach to procedures and guidance has evolved over the six decades of nuclear power operation as a result of a continued focus on excellence in nuclear power operation. This resulted in the implementation of human factor engineering in the development of procedures and guidance as well as a systematic approach to training plant personnel on these procedures. Procedures and guidance have been developed for a wide range of possible events to ensure that the plant staff has a resource to respond to any event that may occur.

Glossary

BDBA Beyond Design Basis Accident is an event that is outside of the plant design basis and is similar in meaning to design extension conditions.

BWR Boiling water reactor.

Design extension conditions A set of events that are beyond the design basis of the plant for which mitigative actions should be taken to ensure safety.

Emergency operating procedure A set of instructions that are to be implemented following an unintentional reactor trip signal or a signal for injection of emergency core cooling water.

Guidance Any set of instructions that are recommended to be implemented under prescribed plant conditions.

Owners group A group of plant owners with similar plant designs (usually by reactor vendor or reactor type) that fund development programs common to their plant designs.

Procedures A set of instructions that are *required* to be implemented verbatim under prescribed plant conditions.

PWR Pressurized water reactor.

Severe accident guidance (SAG) A set of recommended actions that are to be implemented if significant damage to the reactor fuel is diagnosed.

Severe accident guidelines (SAGs) Individual recommended actions for a specific goal; collectively, the guidelines form the guidance.

Introduction

One of the first efforts to assess the potential impact of an accident beyond the plant design basis was reported in the WASH-740 report, sometimes referred to as the Brookhaven Report (AEC, 1957) in early 1957. In that report, the radiological consequences of an accident more severe than the design basis loss of coolant accident, called the maximum hypothetical accident, were evaluated. The report evaluated three cases in which the worst case assumed no mitigation by a containment building. The report emphasized that distance between a nuclear facility and the nearest population could mitigate the hazards associated with a major radiological release.

Later in 1957, an accident in the United Kingdom at the Windscale facility (Arnold, 2007) led to a large radiation release. Even though the Windscale facility, which was used for production of fissile material for military applications, differed significantly from commercial light water reactors, this accident pointed out that large radiation releases from nuclear facilities were possible.

As discussed in Bley and Malsch (2021a,b) a technical basis, referred to as TID-14844 (AEC, 1962), was developed in 1962 as guidance for demonstrating compliance with the siting criteria found in 10 CFR 100 (US Government Publishing Office, 2020a). The TID-1844 guidance was based on very simple and very conservative calculations assuming a large release associated with an unlikely maximum credible accident but giving some credit for reductions associated with engineered safety features, including the containment. Using this guidance, as reactor operating power level for proposed new plants increased or the proximity to population centers decreased, the need for additional safeguards to reduce the potential radiation releases from the maximum hypothetical accident increased.

After the Three Mile Island Unit 2 accident (Skillman and Rempe, 2021), significant research was undertaken to improve the understanding of the chemical and physical processes that can occur during an accident in which the core is severely damaged. This new knowledge permitted the development of guidance for the nuclear plant operator actions to mitigate the consequences of such events. Technology advancements also enabled the development of new equipment that could also be used to mitigate the consequences of these accident that needed to be considered in the new guidance. This article provides details of guidance for beyond design basis accidents.

Plant conditions

The IAEA Safety Glossary (IAEA, 2018) defines five plant states as shown in Fig. 1. These plant states indicate the degree of safety threat associated with that state, ranging from operation states to accident conditions. The left-most three states constitute operation within the plant design basis. The right-most two states constitute design extension conditions. As noted in the Introduction, this chapter focuses on the guidance provided for the plant staff when the plant state is outside of its design basis. These conditions are called design extension conditions (DECs) in the IAEA Glossary because the range of possible events is virtually limitless, but certain events outside the design basis can be reasonably mitigated by informally extending the design basis but under a different set of regulatory requirements. Lutz and Williamson (2021) focuses on the guidance provided for operation within the plant design basis. In the United States, DECs are more commonly referred to as beyond design basis events.

There are two distinct set of procedures and guidance to provide assistance to the plant staff in responding to these DECs (also known as BDBAs). The first set of procedures and guidance is applicable to accidents that are progressing toward significant core damage and are beyond the scope of traditional emergency operating procedures, such as an extreme external event. For these types of events, additional guidance beyond the emergency operating procedures is needed. The goal of this BDBA guidance is to arrest the accident progression before significant core damage occurs. The Extensive Damage Mitigation Guidelines (EDMG) and the FLEX guidance discussed later are examples of this type of guidance. The second set of procedures and guidance is applicable to accidents that have already progressed to significant core fuel damage. The goal of this severe accident guidance is to prevent or minimize challenges to the remaining fission product barriers. The Severe Accident Guidelines are an example of this type of guidance.

DECs are postulated accident conditions that are not considered for design basis accidents, but that are considered in the design process for the facility in accordance with a best estimate methodology, and for which releases of radioactive material are kept within acceptable limits. In the United States, these conditions are frequently called Beyond Design Basis Accidents (BDBA). A discussion of design basis versus licensing basis in the United States is provided in Lutz and Williamson (2021); in this chapter, the term design basis is used exclusively although it may be the licensing basis for some plants.

Fig. 1 Five plant states identified by IAEA (2018). IAEA (2016) *IAEA Safety Glossary: Terminology Used In Nuclear Safety and Radiation Protection, 2016 Revision*. International Atomic Energy Agency.

History of BDBA and DEC

The process for creating new regulatory requirements for mitigating accidents not considered in the original design basis of the plant differs significantly between the United States and regulatory bodies in Europe and elsewhere (e.g., China, Japan, Russia, etc.). However, the end result can be remarkably similar in many cases. While the European regulators are attentive to the regulators in the United States, in some cases, they have developed approaches that are different from the regulators in the United States as discussed in the following.

In the United States, the Nuclear Regulatory Commission (NRC) can require safety enhancements for plants through the use of an Order if the majority of the Commissioners can justify a finding that there is not adequate protection of the health and safety of the public (Bley and Malsch, 2021a,b). As the word implies, an Order is a requirement handed down by the Commissioners with instructions for the NRC staff to implement. If that finding cannot be made, then the Commissioners can direct the NRC staff to initiate rulemaking to require safety enhancements. In the latter case, any safety enhancements would need to be shown to be cost beneficial using established processes; this is known as the Backfit Rule (US Government Publishing Office, 2020b). This is one instance in which the regulatory process in the United States and that in western Europe differ significantly as discussed below. In the United States, such safety enhancements have come to be known as beyond design basis accident (BDBA) requirements.

In western Europe, typically, the regulatory body and the plant owner/operator work more collegially in determining enhancements to plant safety. The European regulators are not required to consider cost versus benefit, only the safety benefit itself. In Europe, these same safety enhancements have become known as DEC requirements.

There are three instances of importance to BDBA and DEC enhancements:

- After the accident at Three Mile Island Accident Unit 2 in 1979 to correct numerous weaknesses exposed by the accident;
- After the terrorist attacks on the New York City World Trade Center and the Pentagon in 2001 to add additional protections for prevention and mitigation of a terrorist attack on a commercial nuclear power plant; and
- After the accident at Fukushima in 2011 to add additional protections against extreme external events that are beyond the plant design basis.

In addition, after the wave of terrorist attacks in Europe in the 1970s and 1980s, the regulators in Belgium and Switzerland worked with plant operators to develop “bunkered” or “hardened” capabilities to maintain core and containment cooling in the event of a terror attack by airplane or explosives. Each of these is discussed below.

Three Mile Island Unit 2 accident

After the Three Mile Island Unit 2 accident (see Skillman and Rempe, 2021), the US Nuclear Regulatory Commission required a number of changes in the “design basis” of each plant in the United States (NRC, 1980, 1982). Although the design basis was enhanced through these requirements, there was no requirement for beyond design basis enhancements (e.g., severe accident mitigation) at that time. The design basis requirement for maintaining adequate cooling of the reactor core and the containment remained the central focus. The only requirement that could be considered beyond design basis was to provide procedures and training for mitigating core damage accidents. The strategies developed by the Owners Groups to satisfy this requirement were based on the boundary condition that the core remained in the reactor vessel and in a coolable geometry using design basis systems and equipment.

It was only during the 1980s that beyond design basis accidents began to be studied by regulatory bodies and industry worldwide, but especially in the United States and western Europe. The studies included both prevention and mitigation aspects of beyond design basis accidents which were also called severe accidents.

Severe accident prevention studies

The study of prevention of severe accidents focused on identifying the vulnerabilities of commercial nuclear power plants using Probabilistic Risk Assessments (PRA), also frequently called Probabilistic Safety Analyses (PSA) in Europe (see Modarres and Kim, 2021). PRA studies used the same fault tree and event tree methods pioneered in the commercial aviation industry to identify all of the scenarios in which the reactor core could be damaged. The first such study using this methodology was actually completed before the accident at Three Mile Island Unit 2 (NRC, 1975), but it used a generic plant design so that it did not truly represent any individual plant. The first detailed plant PRAs were completed for the Zion and Indian Point plants in the USA in response to an Order by the US NRC to show why these two plants, whose surrounding population density was greater than any other plants in the United States, should be allowed to continue to operate. Following completion of these studies and a finding that the plants should be allowed to continue operation, similar studies were required by regulators in the United States (NRC, 1988) and western Europe. Plant operators made safety enhancements to their plants when significant vulnerabilities were identified.

Severe accident mitigation studies

Significant resources were expended by both the regulators and the industry to understand and construct simulation models of the physical and chemical processes that could occur during an accident where the reactor core was severely overheated and melting. These research programs were sometimes carried out quite independently in the United States (see [IDOR, 1984](#); [NRC, 1983](#)) and in Europe (see [Micaelli et al., 2005](#)) although there was significant knowledge sharing between the United States and European programs. The United States and European sponsored research has been carried on continuously since the 1980s; the references provided are only a snapshot in time of the programs. This research was used to develop and refine computer-based severe accident simulation codes, such as the Modular Accident Analysis Program (MAAP)¹ ([EPRI, 1991](#)), Methods for Estimation of Leakages and Consequences of Releases (MELCOR) ([NRC, 1986](#)) and more recently Accident Source Term Evaluation Code (ASTEC) ([Chatelard et al., 2014](#)). Although the MAAP and MELCOR simulation codes were developed in the United States, they were also widely used in Europe and Asia. Organizations updated their analytical tools as usage expanded beyond their original focus and as new research information becomes available.

In the 1980s, as severe accident simulation progressed into modeling the behavior of a degraded reactor core, it was judged to be sufficiently robust to begin developing emergency response guidance. At this time, there were large uncertainties in some phenomena (chemical and physical processes). The first attempt to develop severe accident guidance (SAG), or severe accident management guidance (SAMG) as it is sometimes called, was carried out in the late 1980s in coordination with development of a technical basis ([EPRI, 1992](#)) that could be used by each of the Owners Groups in the United States. Each of the Owners Groups then developed generic severe accident guidance (see [Lutz and Williamson \(2021\)](#) for a discussion of Owners Group activities in Emergency Procedures). While the format of the SAG for each Owners Group differed, the overall strategies were identical. The format differences were primarily due to the oversight provided by each Owners Group. The initial version of these was made available to plant operators in the 1994–96 time frame. Similar to the generic EOPs that were discussed in [Lutz and Williamson \(2021\)](#), these were also made available to all international members of each Owners Group. More detail on the Owners Group SAG is provided below.

The IAEA has recently updated guidance for development and implementation of severe accident programs ([IAEA, 2019](#)) which is based on their original 2003 guidance ([IAEA, 2003](#)). The Annex in [IAEA \(2019\)](#) provides additional detail on severe accident management guidance in France, Germany, Japan, and the United States. The severe accident guidance for CANDU Pressurized Heavy Water Reactor (PHWR) plants is similar to the PWR approach in the United States.

In the United States, each plant operator committed to implementing the Owners Group generic SAG by the end of 1998 as a condition to closing the regulatory severe accident issue ([NEI, 1991](#)). In western Europe, various agreements were reached between the plant operators and their regulatory authority concerning implementation of SAG for their plants. It is noteworthy that, with the exception of France and Germany, the European plant operators chose to adopt the Owners Group SAG methodology, including the Russian VVER PWR plant owners in eastern Europe ([Ludovit, 1999](#); [EC, 2014](#)).

Containment hydrogen control

As discussed in [Skillman and Rempe \(2021\)](#), the accident at Three Mile Island Unit 2 revealed that hydrogen generated from zirconium-water reactions in an overheated core could accumulate in the containment in sufficient quantities to become flammable. Although the hydrogen combustion event at TMI-2 did not challenge its containment, there was concern that the resulting pressure spike from hydrogen combustion events could challenge the integrity of containments during other severe accident scenarios, particularly scenarios occurring in other containments with lower design pressures. As a result, the US NRC published, 10 CFR 50.44 “Interim Requirements Related to Hydrogen Control” in 1981 ([US Government Publishing Office, 2020c](#)). This regulation had different effects on different reactor/containment designs. The major impact of this regulation on Mark I BWR Containments was to require containment (drywell) inerting (with nitrogen) and to eliminate containment purging as a post-accident combustible gas control scheme. Subsequent studies led to requirements for inerting of Mark II BWR containments and a requirement for post-accident hydrogen control systems for Mark III BWR containment as well as PWR ice condenser containment plants. Both the BWR Mark III plants and the PWR ice condenser plants chose to use hydrogen igniters connected to an a.c. power emergency bus.

Subsequent studies using PRA methods identified the risk significance of station blackout events without a.c. power recovery prior to core damage. In these scenarios, the hydrogen igniters were not operable due to the loss of a.c. power emergency buses which led to failure of the primary containment due to hydrogen burns. This led to a requirement to provide an alternate highly reliable a.c. source to power at least one train of the igniters for all PWR ice condenser containment and BWR Mark III plants ([NRC, 2008](#)).

Other changes required by the NRC and in the 1985 update of the 10CFR 50.44 rule included the containment hydrogen (PWRs and BWRs) and oxygen (inerted BWR containments only) monitoring capability as well as hydrogen recombiners capable of controlling hydrogen generation for design basis accidents.

Hydrogen combustion in large PWR containments was also found to challenge containment integrity under certain low probability conditions. Development of passive autocatalytic hydrogen recombiners, started in the 1980s and reached a state where they were offered commercially in the mid-1990s ([AECL, 1996](#)). At the recommendation of some national regulatory bodies in western Europe, they were installed in PWR containments starting in the mid-1990s (e.g., at Tihange and Doel in Belgium per the

aforementioned reference). Note that some additional western European regulatory bodies recommended these passive autocatalytic hydrogen recombiners after the Fukushima accident in 2011 (NENE, 2013).

EPRI technical basis report (TBR)

The EPRI TBR (EPRI, 1992) was a groundbreaking report in that it was the first attempt to identify all of the potential impacts of mitigative actions by the plant emergency response staff during a severe accident. Up to this time, a large number of probabilistic safety analyses (PSAs) (see Fleming, 2021), had been performed to identify and quantify the probability of a large release of radioactivity from the plant following a core damage event. For the most part, these PSAs did not model interventions but merely modeled an unabated event progression. The reason for this was the absence of a sound technical basis for modeling possible interventions as well as the absence of methods for modeling human reliability of such actions.

The starting point for the TBR was the myriad of PSA analyses performed with computer simulation codes (primarily MAAP and MELCOR) for the various PWR and BWR plant designs. At each point in the accident progression, the best estimate results of possible operator actions on the accident scenario were identified based on severe accident experiments performed world-wide, first principles of the various physical and chemical processes, and information from other industrial processes.

The report was divided into two volumes. The first volume contained diagnostics to determine the state of the reactor coolant system (actually the reactor core) and the containment during a severe accident and major effects of various Candidate High Level Actions (CHLAs) that could be taken for each core and containment state. Because of uncertainties in severe accident phenomena, both the positive and negative impacts of implementing each CHLA were identified. Volume 2 contained the technical basis for each severe accident phenomena postulated during a severe accident as well as the effect of implementing mitigative actions (i.e., severe accident management strategies).

Three “RCS States” were identified as:

- “Oxidized” (OX)—an intact core with significant oxidation,
- “Badly Damaged” (BD)—a partially relocated core but still in-Vessel, and
- “Ex-Vessel” (EX).

Four “Containment States” were identified as:

- “Closed and Cooled” (C),
- “Challenged” (CH)—but still intact,
- “Impaired” (I) and
- “Bypassed” (B).

Fifteen CHLAs were presented in the report including:

- Inject into the RPV/RCS
- Depressurize the RPV/RCS
- Spray within the RPV (BWRs)
- Restart the RCPs (PWRs)
- Depressurize the Steam Generators (PWRs)
- Inject into (Feed) the Steam Generators (PWRs)
- Spray into Containment
- Inject into Containment
- Operate Fan Coolers
- Operate Hydrogen Recombiners
- Operate Hydrogen Igniters
- Inert Containment with Noncondensibles (BWRs)
- Vent Containment
- Spray Secondary Containment
- Flood Secondary Containment

Two special considerations were also presented: External cooling of the RPV/RCS and Steam Inerting/De-inerting of the Containment.

B&W owners group (B&WOG) and combustion engineering owners group (CEOG)

The B&WOG and CEOG used the CHLAs directly from the EPRI TBR along with the positive and negative benefits of implementing those actions directly from the EPRI TBR to develop their basic generic SAG. Special considerations for their plant design features (e.g., B&W once-through steam generators and CE heat removal capability with containment spray recirculation) were included in their respective SAG. Table 1 provides an example diagnostic matrix for these plants.

For each combination of RCS and Containment states (see Table 1), a set of applicable CHLAs is presented in the SAG. There is some prioritization of the applicable CHLAs within each combination of RCS/Containment states. For example, containment

Table 1 Example diagnostic matrix for CE or B&W plant (EPRI, 1992).

<i>Example diagnostic matrix</i>				
<i>Core state description</i>	<i>Containment state description nomenclature</i>			
	<i>Closed/cooled (CC)</i>	<i>Challenged (CH)</i>	<i>Impaired (I)</i>	<i>Bypassed (B)</i>
Oxidized (OX)	OX/CC	OX/CH	OX/I	OX/B
Badly damaged (BD)	BD/CC	BD/CH	BD/I	BD/B
Ex-vessel (EX)	EX/CC	EX/CH	EX/I	EX/B

venting would only be applicable for the “CH” (Challenged) containment state in combination with either the “BD” (Badly Damaged) or “EX” (Ex-Vessel) core states. Additional detail regarding specific SAG from these two Owners Groups is not available in the open literature.

This generic SAG was intended only for use by the plant Technical Support Center (TSC) staff. For both of these plant types, the main control room staff would continue using their plant EOPs. If any differences in guidance were encountered, they would be discussed between the main control room staff and the TSC. For example, the SAGs may provide guidance to reduce or terminate containment spray to steam inert the containment to prevent a hydrogen burn, whereas the EOPs would continue use of containment spray until the containment was reduced to near atmospheric pressure. The CEOG SAG also included some computational aids to assist the user in identifying the applicable core and containment states. The B&WOG SAG and the CEOG SAG transition from the EOPs to the SAGs based on a high core exit thermocouple indication that is indicative of inadequate core cooling.

Westinghouse Owners Group (WOG)

The Westinghouse Owners Group developed a unique symptom-based diagnostic process (Lutz et al., 1995) based on seven plant parameters: SG Level, RCS Pressure, Core Temperature, Containment Water Level, Containment Pressure, Containment Hydrogen and Fission Product Release Rate. These parameters were then arranged in order of importance from an accident progression perspective and numerical values defined for each parameter that represented a need to implement a mitigating strategy. Strategies were incorporated into step-wise guidelines corresponding to each of the seven symptom based parameters.

A unique feature of the WOG SAG was the development of a separate guideline for control room staff that recommended continuation of steps already attempted in the EOPs that were unsuccessful in arresting the accident before core damage occurred. The remainder of the guidelines were for use by the TSC staff. This approach clearly separated the design basis training for plant operators (restore core cooling) with the beyond design basis focus of maintaining fission product barriers intact (or mitigating fission product releases if a barrier is breached). Like the B&WOG and the CEOG, the WOG transitions from EOPs to the SAGs based on high core exit thermocouple indications.

Another unique feature of the WOG SAG was the symptom based Computational Aids to assist the user in cases where direct measurement might not be available. Key aids included: Required Water Flow Rates to Restore Core Cooling, Containment Flammability (based on hydrogen concentration) and, Containment Volume versus Water Level.

The WOG SAG was updated in 2001 based on issues identified during plant specific implementation as well as new research findings between 1994 and 2001.

BWR Owners Group (BWROG)

Initially, the BWR Owners Group chose to integrate their SAG into their EOPs. The BWROG used an expert team to develop the operator actions from the TBR and other documents. These actions were reviewed by the BWROG and eventually approved for the SAG.

The BWROG designed a transition from the generic EOPs to the generic SAGs based on loss of adequate core cooling. The transition was established because severe accident conditions were not as easy to determine as were conditions within EOP space. It was expected that help from the TSC would be available to determine the appropriate plant conditions for initiating use of the SAGs.

The CHLA from the TBR and insights from other documents were used to develop the SAG guideline changes. SAG Rev. Zero (0) was prepared in 1996 and following some demonstrations Rev. One (1) was used in the US to implement SAGs at the end of 1998.

Terrorist activities in Europe

In the 1970s and 1980s, a significant number of terrorist attacks took place in Europe (Walker et al., 2010). As a result, the regulatory agencies in many European countries studied methods to keep commercial nuclear power facilities safe from bombings and takeovers. Only the Belgian and the Swiss regulators recommended that plant operators in those countries develop hardened facilities where key systems for plant shutdown and the plant operating staff would be protected from such attacks. These became known as

hardened or bunkered systems in Belgium and Switzerland. The following two paragraphs describe how such systems were implemented at the Tihange plant in Belgium and the Beznau plant in Switzerland.

Besides regular primary level safety systems, the Belgian Tihange has secondary level safety systems that can autonomously keep the power plant safe during large external accidents, such as the crash of an aircraft, external explosions or loss of the water level in the reactor coolant system (FANC, 2011). The primary level systems for core cooling and steam generator heat removal have two or three redundant trains of safety. The secondary level systems are housed in a hardened structure that can withstand aircraft or bombs and contain similar systems for core cooling and heat removal. The secondary level systems also use water from underground water tables as the primary heat sink instead of the normal heat sink which is the Meuse river.

In Switzerland, each reactor unit of the Beznau station has been equipped with an emergency structure containing an independent set of emergency systems called the NÄhrüstung NOTstand, or NANO emergency retrofit system. The systems housed in the structure include additional water injection systems for reactor emergency shutdown, feeding the steam generators, a 50 kV emergency power line, and a diesel generator. They are heavily protected (bunkered) from external hazards and, if needed, are able to cool and shut down the power plant without human intervention for 72 h. With at least 1.5 m thick concrete-steel housings, these buildings protect critical systems from external agents such as earthquakes or plane crashes (Cecchi, 1993).

Chernobyl

As discussed in Sich (2021), the 1986 accident at the Chernobyl Unit 4 power station was a catastrophic event initiated by an ill-timed experiment to try to use latent energy in the main turbine during coastdown. The timing of the experiment would have been in direct contradiction to regulations governing the conduct of nuclear power plants in the United States and western Europe. In response to the event, US regulators (NRC, 1987) and the European regulators emphasized the importance of operator training, maintaining the plant within the bounds of the safety analyses while performing tests and experiments at operating reactors, and promoting safety culture. The Institute for Nuclear Power Operations (INPO) developed voluntary guidance that required a reactor engineer to be involved in any tests that could affect core reactivity. Canadian regulators also made several changes to constrain positive void coefficients in their CANDU PHWR plants.

However, the catastrophic release of fission products from the accident caused European regulators to have concerns about the overall health and safety of their citizens. As a result, many regulators in western Europe recommended that plant operators install filtered vents on the containment to reduce the amount of fission product released if containment venting should become necessary. One of the first installations of filtered containment vents was at the plants in Sweden (Kärnkraftsäkerhet, 1997). As these filtered vents were added to plants, it became necessary for the SAG to be updated to reflect this change. It is known that the Westinghouse Owners Group developed an enhancement to their generic SAG for these European plants (Milhalina and Jalovec, 2013). However, little information is available in the open literature.

World trade center and pentagon attacks

On September 11, 2001, terrorists crashed two commercial aircraft in the World Trade Center in New York City, as well as the Pentagon Building in Washington, DC. The US NRC developed new regulatory requirements to enhance the safety of nuclear plants in the United States due to terrorist activities. The NRC issued an Order requiring all plants to upgrade security, provide mitigative strategies and capabilities for spent fuel pools, provide strategies for loss of command and control of the plant and, provide strategies for maintaining core and containment cooling in the event of a terrorist attack at the plant (NRC, 2002).

In response, the industry developed a set of guidance for implementation of the Order that was approved by the NRC (NEI, 2006). One of the major tenants of the guidance was the capability to maintain spent fuel pool, core, and containment cooling in the event of a terrorist attack that destroyed a quadrant of the plant (often referred to as a Loss of Large Area event) and resulted in a loss of all internal power distribution (loss of all a.c. and d.c. power distribution within the plant).

The net result of this guidance was the procurement of portable equipment for maintaining spent fuel pool, core and containment cooling at a remote location on the plants site that could be rapidly connected in the event of such an event. This portable equipment became known as the B.5.b equipment. A high-level regulatory requirement for the B.5.b equipment and associated programmatic topics (e.g., staffing, guidance, training, etc.) was developed as 10CFR50.54(hh) (U.S. Government Publishing Office, 2020d). While this regulation is specifically focused on aircraft crashes into a nuclear power plant site, the guidance and equipment would also be useful for other terrorist-initiated events that cause physical damage to the plant.

There were also procedures and guidelines developed that became known as the Extended Damage Mitigation Guidelines (EDMGs). These guidelines included instruction on the hookup and use of the portable equipment and also methods to determine the measurement of key plant parameters. The loss of internal power distribution made instrument readouts unavailable. The event could also make the control room unavailable for operating equipment and as a focal point for command and control.

This B.5.b equipment and EDMG differs from the Diverse and Flexible Coping Strategies (FLEX) safety enhancements (NEI, 2012) described in the following section in several important ways:

- Only one set of B.5.b equipment was required for the entire plant site,

- The hook-ups for the portable equipment did not require consideration of beyond design basis external events (e.g., floods, tsunami, etc.),
- It was assumed that the plant could be tripped (scrammed) several tens of minutes before systems became unavailable,
- No internal power distribution (a.c., power or d.c. power) is available for EDMGs.

After the programs were implemented at each plant, the NRC did not develop inspection guidance. The readiness of the equipment and training was left to each plant owner. Following the Fukushima accident in 2011 (see below), NRC audits of maintenance and training of the B.5.b equipment by some plant operators revealed weaknesses at some plants. As a result, in mid-2011, the NRC required a detailed description of each plant operator's B.5.b program in relation to the 10CFR50.54(hh) requirements (NRC, 2011). In 2007, the BWROG addressed issues to add the B.5.b capability to both SAG and EOPs where appropriate. For PWRs, the guidance for use of the B.5.b capability is a separate guideline from the EOPs; reference was made in the SAG to the B.5.b guidelines in the 2012 SAG upgrades after Fukushima.

Fukushima

As discussed in Mizokami and Rempe (2021), the events at the three operating units of Fukushima Daiichi revealed weaknesses in the plant coping capability to respond to a Beyond Design Basis External Event (BDBEE). The weaknesses included plant design features, accident management procedures and guidance, and offsite emergency response. As discussed in Mizokami and Rempe (2021), significant changes have been made to nuclear reactors worldwide to enhance the coping capabilities for beyond design basis accidents. The global response resulted in many common changes in coping capability but also many differences. This section describes how insights from the Fukushima accident affected SAG in selected countries (Lutz et al., 2016).

United States response

The response to the Fukushima accident in the United States started immediately after the accident and initially took two separate paths. The first path was led by the regulator, the US NRC, while the second path was led by the nuclear power industry. The regulator and the industry worked together to formulate a set of enhancements to the capability of plants to respond to a BDBEE.

The focus in the United States was clearly on enhancements to guarantee continued core, containment and spent fuel pool cooling in the event of beyond design basis accidents, particularly those resulting from extreme external events. The FLEX initiative (NEI, 2012) added another layer to the beyond design basis mitigation capability previously implemented in response to the 2001 Terrorist Attacks (NEI, 2006).

The FLEX concept involves strategies to maintain core, containment and spent fuel pool cooling for a wide range of BDBEES that result in the loss of all a.c. power (onsite and offsite) as well as access to the ultimate heat sink for an indefinite period of time. The strategies rely upon a combination of fixed, in-place and portable equipment that would be protected from the BDBEE. The FLEX equipment includes portable high- and low-pressure pumps, diesel generators, fire trucks and debris clearing equipment. In addition to the FLEX equipment, the enhancements include: procedures and guidance for using the FLEX equipment (called FLEX Support Guidelines, or FSGs), staffing and communications plant walkdowns to ensure adequate flood protection, seismic evaluations, and enhanced offsite emergency response preparedness. Unlike the B.5.b enhancements, it was required to have one set of FLEX equipment per reactor unit plus one complete spare. The FLEX hook-ups for the FLEX equipment had to consider beyond design basis flood levels.

Each Owners Group developed generic FLEX Support Guidelines (FSGs) that were then made plant-specific by each plant operator. Most of the FSGs focused on diagnosing plant conditions for use of FLEX equipment and guidance on hook-up of FLEX equipment. However, one important FSG focused on alternate methods of determining key plant conditions when normal instrumentation in the control room is not available (Lutz et al., 2016). Those alternate methods include the use of mechanical measuring devices (e.g., local gauges), using portable read-out devices at specific locations and inferring parameters from other available indications.

New regulatory requirements in 10 CFR 50.155 (U.S. Government Publishing Office, 2020e) for procedure/guidance enhancements (including FSGs) focused on maintaining core, containment and spent fuel pool cooling following an extreme external event that is beyond design basis. However, no regulatory requirements for mitigation of an event once core damage occurs (e.g., severe accident guidance) were initiated. The requirement in the Backfit Rule, 10CFR50.109, for cost beneficial enhancements of proposed new regulatory requirements could not be justified for SAG. Nevertheless, the industry voluntarily undertook an update of the Owners Group generic SAG to incorporate lesson learned from the Fukushima accident. The two most notable enhancements were guidance for detecting and mitigating hydrogen accumulation in buildings adjacent to the primary containment and guidance for water addition and venting for Mark I and Mark II BWRs (NEI, 2013).

The Fukushima accident occurred in the same time frame as the consolidation of the three Owners Groups from PWR vendors into a single Owners Group called the PWR Owners Group (PWROG). The enhanced SAG developed by the PWROG includes Fukushima lessons learned and was made available to all PWROG members. A key feature of the updated PWROG SAG is the development of Technical Support Guidelines (TSGs). Key TSGs included a "Plant Capabilities" guideline that list all of the resources (including B.5.b equipment and FLEX equipment) at the plant that could be used in an emergency and an "Instrumentation"

guideline (Lutz et al., 2015) that can be used to validate instrument readings. Due to the proprietary nature of the new PWROG SAG, only limited knowledge of their contents is available in the open literature (Labarge and Lutz 2013; Prior, 2016).

The BWROG enhanced SAG was also updated to include Fukushima lessons learned. In the SAGs, the concept of Severe Accident Water Addition (SAWA) and Severe Accident Water Management (SAWM) were integrated into the SAG. SAWA guidance focuses on ensuring that any ex-vessel core debris is stabilized and SAWM guidance focuses on preserving the use of the suppression chamber vent during a severe accident. Another example is improvement in the generic Technical Support Guidelines, which support SAGs, for determination of control parameters, and of plant conditions, and SAG support actions. These improvements include some generic best estimate calculations to help validate (or refute) parameter indications and determine the best estimate of the plant condition. Like the PWROG SAG, little information is available in the open literature because the BWROG SAG is proprietary.

European response

The regulatory situation in Europe differs from that within the United States. Within Europe, each country has its own regulatory body. There is also a wide range of reactor designs, including those of US design origin, but also Swedish Boiling Water Reactors, German and French Pressurized Water Reactors, Russian VVERs, Canadian PHWRs, and British Gas-cooled Reactors. Prior to the Fukushima accident, significant efforts had been made to harmonize regulatory requirements, led by international organizations such as the International Atomic Energy Agency (IAEA), the Western European Nuclear Regulators Association (WENRA) and the European Nuclear Safety Regulators Group (ENSREG).

Following the Fukushima accident, both WENRA and ENSREG acted quickly to specify a “stress test” to be performed by all European Union (EU) member state plants (Switzerland and Ukraine, who were not EU states, also participated). Each national regulator required their licensees to perform the assessments (sometimes called “complementary safety assessments”) using WENRA and ENSREG guidance (ENSREG, 2011). These assessments covered three areas:

- Initiating events (earthquake, flooding and other extreme natural conditions);
- Consequential loss of safety functions (prolonged total loss of electrical power supply, prolonged total loss of the primary ultimate heat sink, combination of the two);
- Accident management issues for core melt scenarios and degraded conditions in the spent fuel pool

The results of the stress tests (European Union, 2014) were used to identify weak points and develop solutions, increasing the plant’s overall robustness in these areas. A number of safety enhancements were already being considered before the Fukushima event, but different plants and countries were at different stages of implementing needed enhancements. Many plants had also improved severe accident management capabilities by installing fixed mitigation systems such as passive hydrogen recombiners and filtered vent systems. In addition, as discussed in Mizokami and Rempe (2021), Fukushima brought new lessons: the possibility of simultaneous severe accidents in multiple units on a site, the possibility of loss of all instrumentation early in an event, and others, which now needed to be addressed. In Europe, both mobile/temporary and fixed equipment backfits were implemented. These backfits include both preventive (pre-core damage) and mitigative (severe, post-core damage) measures.

As an example, the new Reference Safety Levels issued by WENRA (WENRA, 2014) include requirements that events inside and outside the design basis must be analyzed and appropriately addressed (including the use of additional installed or temporary equipment, where appropriate). The Design Extension Conditions (DECs) should consider those events not leading to core damage (DEC-A), and, importantly, also those events where core damage occurs - severe accidents (DEC-B).

Differences between the United States and Europe

Based on the requirements recommended by a majority of regulators in Europe and in the United States, there are three important differences in the approach to BDBE/Design Extension Conditions (Lutz and Prior, 2016):

1. In Europe, the majority of regulators now require filtered containment vents and autocatalytic hydrogen recombiners capable for mitigating consequences of an accident that results in significant core damage. Neither of these is required in the United States.
2. In Europe, SAG is required by the majority of regulators and is reviewed and approved by the regulator. In the United States, SAG is a voluntary effort that plant operators have committed to implement and maintain; the level of regulatory oversight to ensure that the commitments are maintained is under development.
3. In Europe, many of the regulators are requiring that instrumentation be installed that is qualified for operation under accident conditions resulting from a severely damaged core. In the United States, plant operators use guidelines developed by the Owners Groups to validate indications from existing instrumentation.

The BWROG also demonstrated that existing plant instrumentation, when properly validated, could provide sufficient information to arrest a BDBE with core damage without need of additional instrumentation. Both the BWROG and the PWROG provided information for validation of plant instrumentation for BDBEs in Technical Support Guidance to their SAG.

Japanese response

The immediate response of the Japanese regulator was to shutdown all plants in Japan until a thorough safety review could be conducted. Investigations were initiated to upgrade plant capability to withstand extreme external events (preventive measures), including earthquakes and tsunamis (i.e., prevent an event resulting from an extreme external event). Other investigations have been carried out to develop capability to maintain core, containment and spent fuel cooling in the event of an extreme external event that overwhelms the preventive measures. Finally, mitigation equipment and guidelines have been developed to mitigate challenges to fission product boundaries in the event of a core melt event, such as portable pumps for water injection to the containment spray system, hydrogen control systems using passive autocatalytic recombiners and filtered containment vents.

Summary

Accidents beyond the plant design basis have been considered from the earliest days of commercial nuclear power. Modeling of this class of accidents was quite simplistic and, as a result, the earliest considerations focused on siting plants away from population centers and providing systems and structures to reduce the amount of radioactive materials that might be released during such an accident. After the Three Mile Island Unit 2 accident, significant research was undertaken to improve the understanding of the chemical and physical processes that can occur during an accident in which the core is severely damaged. This new knowledge permitted the development of guidance for the nuclear plant operators to take actions to mitigate the consequences of such events. Technology advancements also enabled the development of new equipment that could be used to mitigate the consequences of these accident. Capabilities to mitigate beyond design basis accidents was further enhanced as a result of terrorist attacks throughout the world and from lessons learned from the accident at Fukushima in 2011.

Glossary

Advisory Committee on Reactor Safeguards (ACRS) Independent Advisory Committee to the US Nuclear Regulatory Commission (NRC) that is statutorily mandated by the Atomic Energy Act of 1954, as amended.

Anticipated Operational Occurrences (AOOs) Operational events that constitute a perturbation in normal operations that are anticipated and considered in the design basis of the plant.

Anticipated Transient without Scram (ATWS) One of the “worst case” accidents, consideration of which frequently motivates the NRC to take regulatory action. Such an accident could happen if the scram system (which provides a highly reliable means of shutting down the reactor) fails to work during a reactor event (anticipated transient). The types of events considered are those used for designing the plant.

Atomic Energy Commission (AEC) The Federal agency created in 1946 to manage the development, use, and control of atomic (nuclear) energy for military and civilian applications. The AEC was subsequently abolished by the Energy Reorganization Act of 1974 and succeeded by the Energy Research and Development Administration (now part of the US Department of Energy) and the NRC.

Beyond Design Basis Accidents (BDBAs) Credible but unlikely accidents that are outside the design basis of the plant and fail the success criteria set out in 10CFR20, 10CFR50, and 10CFR100.

Boiling Water Reactor (BWR) A common nuclear power reactor design in which water flows upward through the core, where it is heated by fission and allowed to boil in the reactor vessel. The resulting steam then drives turbines, which activate generators to produce electrical power.

Code of Federal Regulations (CFR) Regulations promulgated by US government agencies. Commercial nuclear energy facilities are governed by 10CFR Parts 1–199 promulgated by the NRC.

Conditional Containment Failure Probability (CCFP) Containment failure probability conditional on a core damage event.

Defense-in-Depth (DiD) A design and regulatory principle that relies on several consecutive and independent levels of protection that would have to fail before harmful effects could be caused to people or to the environment. If one level of protection or engineered barrier were to fail, the subsequent level or barrier would be available. When properly implemented,

DiD ensures that no single technical, human or organizational failure could lead to harmful effects, and that the combinations of failures that could give rise to significant harmful effects are of very low probability.

Design Basis Accidents (DBAs) One category of the postulated accidents used to set criteria and limits for the design and sizing of safety-related systems, structures, and components.

Emergency Core Cooling System (ECCS) Reactor system components (pumps, valves, heat exchangers, tanks, and piping) that are specifically designed to remove residual heat from the reactor fuel rods in the event of a failure of the normal core cooling system (reactor coolant system).

Engineered Safety Feature (ESF) A system, structure, or component that is relied upon during or following a DBE to ensure the capability to prevent or mitigate its consequences such that potential off-site exposures remain below values specified in applicable regulations.

Extended Loss of AC Power (ELAP) An event sequence that results in the failure of all AC power sources at the reactor facility so that only the reactor facility's battery power is available.

Final Safety Analysis Report (FSAR) Document submitted by an applicant that provides information to support the NRC safety evaluation of a proposed facility. It is based on the finalized detailed design of the facility, and it must periodically be updated throughout the life of the facility.

General Design Criteria (GDC) The set of high-level requirements for the design and safety analysis for water-cooled nuclear power plants established to ensure safe reactor operation and to minimize radiological releases.

Individual Plant Evaluation (IPE) A risk analysis (requested in NRC Generic Letter 88-22) that considers the unique aspects of a particular nuclear power plant, identifying the specific vulnerabilities to severe accidents within that plant.

Light Water Reactor (LWR) A term used to describe reactors using ordinary water as coolant, including boiling water reactors (BWRs) and pressurized water reactors (PWRs).

Loss of Coolant Accident (LOCA) Postulated accidents that result in a loss of reactor coolant at a rate in excess of the capability of the reactor makeup system from breaks in the reactor coolant pressure boundary, up to and including Large Break LOCA (LB-LOCA), which is a break equivalent in size to the double-ended rupture of the largest pipe of the reactor coolant system.

Maximum Credible Accident (MCA) A major accident, hypothesized for purposes of site analysis or postulated from considerations of possible accidental events, that would result in potential hazards not exceeded by those from any accident considered credible. Such accidents have generally been assumed to result in substantial meltdown of the core with subsequent release of appreciable quantities of fission products.

National Fire Prevention Association (NFPA) An international nonprofit organization devoted to eliminating death, injury, property and economic loss due to fire, electrical and related hazards.

Operational Basis Earthquake (OBE) Earthquake of magnitude such that plant operations can continue to operate without shutting down for damage inspections.

Pressurized Water Reactor (PWR) A common nuclear power reactor design in which very pure water is heated to a very high temperature by fission, kept under high pressure (to prevent it from boiling), and converted to steam by a steam generator (rather than by boiling, as in a BWR). The resulting steam is used to drive turbines, which activate generators to produce electrical power.

Probabilistic Risk Assessment (PRA) An approach to safety analysis that identifies what can go wrong and quantifies the likelihood and consequences of each scenario. Risk of a facility is presented in terms of the probability of various consequences, including rankings of contributors to the risk and a formal treatment of uncertainty.

Reactor Trip/Reactor Scram An automatic actuation of systems to terminate the fission process in the reactor. The term, "trip," is typically applied to PWRs and the term, "scram," to BWRs.

Safe Shutdown Earthquake (SSE) The maximum earthquake potential for which certain structures, systems, and components, important to safety, are designed to sustain and remain functional.

Safety Analysis Report (SAR) Document submitted by applicant that provides information to support the NRC safety evaluation of a proposed facility. It is based on the detailed design of the facility, and it must periodically be updated throughout the life of the facility.

Single Failure Criterion Requirement that a system, which is designed to perform a defined safety function, must be capable of meeting its objectives assuming the failure of any major component within the system or in an associated system which supports its operation.

Station Blackout (SBO) A class of anticipated operational events involving loss of onsite and offsite AC power.

US Nuclear Regulatory Commission (NRC) The body established by the Atomic Energy Act, as amended, to regulate civilian applications of nuclear power in the United States (formerly, the Atomic Energy Commission).

Introduction

The safety analysis of commercial light water nuclear power plants has been under continuous evolution and improvement since the first reactors were constructed in the 1950s. Practical and operational experience has been gained over the years from knowledge

advancements, experimental investigations and several landmark real-world accidents; this improved understanding is reflected within the rules and guidance set forth in Regulatory Guides and Safety Standards by the US Nuclear Regulatory Commission (NRC), the International Atomic Energy Agency (IAEA) and other international oversight agencies. This article provides an overview of the types of safety analyses that are required to demonstrate design safety and approval for operations with a principal objective of maintaining adequate health and safety to the population. In addition to an overview of the required safety analyses, this article identifies guidance available for performing these analyses and criteria are compared with analyses results. Additional information on this topic may be found in [Martin \(2021\)](#), [Bley and Malsch \(2021a,b\)](#), [Lutz and Williamson \(2021a\)](#), and [Rempe \(2021a\)](#). After providing some historical perspective, the article describes evaluations required for various types of events.

Historical

The Atomic Energy Act of 1946 opened the way for the application of peaceful uses of nuclear energy and for commercial applications to begin to employ the nuclear technology previously used only in defense applications during World War II, and the Atomic Energy Commission (AEC) was established to both promote and regulate this emerging civilian application as well as defense applications. At the time, there was no formalized process for establishing regulatory requirements for the design, construction, operation of nuclear power plants. As discussed by [Bley and Malsch \(2021a\)](#), this would evolve over the following decades as industrial experience was gained and a need was developed for streamlining the licensing review of a rapidly growing industry by the 1960s. Selected historical aspects of regulatory development in the United States that affected reactor safety analyses are highlighted below.

Siting criteria and 10CFR100

Initially, in recognition of the inherent danger to the public of radiation releases, the safety emphasis of the first reactors was focused on siting and proximity to population centers. A siting rule was developed for the relatively low power reactors of the time. This was called the rule of thumb calculation for the distance “R” (in miles) required to separate local population from the site where a reactor of power level “P” (in kilowatts or kW) was located; it was expressed as $R(\text{miles}) = 0.01 * \sqrt{P(\text{kW})}$ such that the dose to a person at a 2.24 mile exclusion radius around a 30 MW reactor would be less than 300 rem ([AEC, 1950](#); [NRC, 1993](#)). This recommendation was made in 1947 by the Reactor Safeguards Committee, which ultimately became the Advisory Committee on Reactor Safeguards (ACRS) (see [Bley and Malsch, 2021a](#)). In their recommendation, the committee discussed siting practices, airborne hazard control, loss of reactor cooling and prevention of energetic events (nuclear and chemical). These concepts would eventually be reflected in modern formalized safety measures and regulatory requirements for the much higher-powered reactors of today.

Defense in depth

One of these measures (beyond remote siting) was the potential use of a “containment” that would in addition to the attenuation of releases from the site offered by distance provide an additional layer of protection from uncontrolled releases of radioactive materials from a presumed accident. For this reason, the Shippingport Atomic Power station, ostensibly the first American commercial power reactor, was situated within a robust containment building. This second layer of protection, a containment building in addition to remote siting, evolved into a principle known today as “Defense in Depth” or DiD in which additional layers of physical and administrative safety measures aimed at prevention as well as mitigation are employed to make commercial nuclear power as safe as possible and radiation exposure “As Low as Reasonably Achievable” often referred to as ALARA (see 10CFR20.113 in [U.S. Government Publishing Office, 2019](#)).

Accidents with radiological consequences

Growing public awareness of the expanding commercial nuclear industry and a concern for adequate federal insurance underwriting through the 1957 Price-Anderson Act (Section 170 of the AEA, as amended) in the event of a large consequential accident, led to the commissioning of a landmark study known as the Brookhaven Report or more commonly today known as WASH-740 ([AEC, 1957](#)), that explored “plausible or credible” potential accidents and associated radiological source terms and consequences. This study examined, among other things, the impact of a loss of cooling accident (LOCA) in which the ability to remove the decay heat has been lost or compromised and found that unless cooling could be restored, melting of the reactor core and melt-through of the vessel releasing radioactive materials to the containment were possible, with eventual penetration of the concrete basement of the containment building (i.e., containment failure). This scenario was later coined “the China syndrome” owing to the notion that molten core materials could continue to move downwards toward China. This growing awareness of potential threats to safe operation of reactors eventually led to the characterization of realizable accidents with consequences, variously referred to as “maximum credible accidents (MCAs),” “limiting accidents” or “design basis accidents (DBAs),” a first step in the goal of eliminating or mitigating unlikely but potentially severe accidents. Eventually, distinction would be made for accidents that are accommodated in the design basis of the reactor and those more extreme accidents that fall outside of the design basis of the plant. Today, the success criteria for addressing a DBA-LOCA, or other such challenges to fuel integrity, are spelled out in 10CFR50.46 ([U.S. Government Publishing Office, 2019](#)), where calculated maximum temperature limits are placed on fuel cladding for such events. As described in Appendix K of 10CFR50, methods for performing such calculations are required to have either prescribed biasing conservatisms to account for uncertainties in the state of knowledge and in actual conditions in the accident (see [Rempe, 2021a](#)).

The “rule of thumb” siting calculation was later replaced by the regulatory requirements of 10CFR100 in which site boundary maximum dose limits from credible but potentially low frequency accidents are prescribed. In meeting requirements for siting, industry was permitted to consider Engineered Safety Features (ESFs) that could mitigate accidents and any resultant releases to the environment by use of containment sprays and safety systems such as the Emergency Core Cooling System (ECCS) as well as protecting containment performance during accidents by specifying maximum containment leakage under accident conditions necessary to meet site boundary requirements of 10CFR100. In this way, regulatory requirements aimed at maintaining “adequate protection” to the public from nuclear power operations were gradually aggregated to be applied to the licensing of subsequent reactor designs.

Standardized design processes and general design criteria

Until the mid-1960s the license reviews of commercial power reactors were considered on a case-by-case basis by the AEC, but the growing numbers of new applications made such a case-by-case safety review process increasingly burdensome and impractical. To alleviate this situation a set of General Design Criteria (GDC) were developed so that designers and reviewers could follow best and approved practices in preparing the safety basis for the plant. These general criteria are described in Appendix A of 10CFR50 (U.S. Government Publishing Office, 2019). These criteria are general, providing high level goals to be met and prescribed design aspects that should be addressed, such as quality control and documentation requirements for safety systems and components; protection against fires and natural phenomena (flooding and seismic events); and sharing of systems and components. These criteria are an accrual of knowledge in reactor design fostering standardization of the safety design process and its documentation in the Safety Analysis Report (SAR) and supporting efficient and consistent regulatory review of submitted license requests (Bley and Malsch, 2021a; Rempe, 2021a).

Safety analyses and the SAR

The modern safety and performance analyses conducted today reflect the lessons learned from accumulated operating experience of reactors since the 1950s. As noted previously, these lessons are reflected in the US Code of Federal Regulations (CFR) Parts 20, 50, and 100 (U.S. Government Publishing Office, 2019), NRC Regulatory Guides as well as in various IAEA guidance documents aimed at promoting best safety practices around the world. It is noteworthy that US regulatory practices strictly follow US laws and regulations and are not always completely harmonious with the equivalent IAEA-recommended standards and practices. US NRC Regulatory Guide 1.70 Rev 3 (NRC, 1978) provides an outline and format of the Safety Analysis Report (SAR), which documents the various analyses required to meet the GDC that are done by the reactor designers and plant owners/operators to demonstrate compliance with all laws and regulations. A similar document, referred to as “The Standard Review Plan” (NUREG 0800) (US NRC, 2020a), serves to guide NRC technical reviewers through the SAR review process.

In particular, SAR Chapter 15, as described in NRC Reg. Guide 1.70 (NRC, 1978) and with more detail in IAEA SSR-2/1 (IAEA, 2016), IAEA SSG2 (IAEA, 2009), and IAEA Safety Guide GSG-4.1 (IAEA, 2004) using a different SAR Chapter numbering system, is dedicated to safety analyses associated with the design basis of the plant and to address the relative likelihood of these accidents according to the following categories: (a) incidents of moderate frequency that are expected to occur several times over the lifetime of the plant (suggesting a frequency of once per year), (b) infrequent events postulated within the design basis of the plant that might or might not occur over the plant lifetime (suggesting a frequency on the order of once in ~40 years or more, and (c) limiting but credible faults that are not expected over the life of the plant but are nevertheless considered because of their potential for a release of a significant amount of radioactive material from the plant.

Conservative versus best estimate and uncertainty quantification approaches

Safety analyses over the years have evolved with respect to the state of scientific knowledge, capabilities of computational resources, sophistication, and accuracy of the underlying models. Early efforts to quantify the risk associated with a core damage accident, such as the Reactor Safety Study (Rasmussen, 1975), relied on bounding analyses and adopted conservative modeling assumptions to quantify the consequences of radiological releases from such events due to uncertainty and knowledge gaps. The use of conservative assumptions has also been reflected in evolving regulatory practices concerning conduct of safety analyses, especially those analyses associated with licensing activities. Analyses associated with the performance requirements of the ECCS during a LOCA are a prime example illustrating the refinement of calculational approaches over time. Such licensing analyses are made using what is referred to as an Evaluation Model, which generally is a computer software model of the reactor system. In this example, the Evaluation Model considers the reactor fuel, coolant pumps, and physics and phenomena required to simulate numerous processes, such as fuel decay heat, coolant flow pressure drops, heat transfer, and chemical reactions (e.g., cladding oxidation in steam). The success criteria for ECCS functions require that the fuel remains coolable following a LOCA with a temporary loss of coolant covering the reactor core. Research gained from experimental investigations led to development of success criteria that ensure fuel coolability, such as during a LOCA transient the peak fuel cladding temperature should remain below 1204 °C (2200 °F) and the local cladding oxidation should be limited to 17%. These success criteria are prescribed in 10CFR50.46. Appendix K to 10CFR50 describes the requirements of the Evaluation Model for such analyses and identifies several prescriptive modeling approaches that assure the analyses are “conservative,” meaning that analyses performed in this way have a “high likelihood” of meeting the success criteria given

uncertainties in the physics and modeling of the system response. Some examples of the prescribed conservative biases include assuming that the reactor decay heat level is 1.2 times the value specified in the ANS Decay Heat Standard (ANS, 1971), that a known high-biased cladding oxidation model be used (Baker and Just, 1962), as well as other similarly conservatively biased assumptions with respect to heat transfer and fluid flow. In this way, uncertainties which could lead to a more pessimistic result can be factored into the licensing analysis, increasing the likelihood that the success criteria are met in all cases. The impact of this approach is that operating power might ultimately be limited to values lower than optimal for energy production in normal operating conditions in order to not exceed the success criteria for the ECCS under accident conditions.

In recognition that unnecessary conservatism in regulatory success criteria can place unnecessary regulatory burden and costs to the licensee, the NRC has been moving toward more risk informed regulatory approaches that attempt to reduce the regulatory burdens to those only necessary to achieve the safety objectives. The original conservative prescriptive approach outlined in Appendix K has been augmented with an alternative “best estimate” approach in which unnecessary prescriptive conservatisms are relaxed to allow for appropriately reduced safety margins relative to the success criteria of 10CFR50.46, provided that uncertainties in the reduced margins are characterized and shown to be within the margins of the regulatory limits.

The performance requirements of a best estimate evaluation model are outlined in NRC Regulatory Guides 1.157 (NRC, 1989) and 1.203 (NRC, 2005). Fig. 1 illustrates the reduction in predictions for peak cladding temperature associated with the use of best estimate methods for calculating peak cladding temperature during a LOCA accident for a PWR. The figure compares the peak cladding temperature estimated with different modeling assumptions to the 10CFR50.46 peak cladding temperature limit. Of these analyses, the conservative modeling guidance of Appendix K yields the highest value, which in this example is below the regulatory limit of 1204 °C (2200 °F). This result follows from assuming 1.2 times the best estimate decay heat and the use of conservative (high biased) cladding oxidation kinetics prescribed in Appendix K. Using a more realistic cladding oxidation model results in a somewhat lowered peak cladding temperature and additional operating margin that could be used by a licensee in requests to reduce unnecessary financial penalties, such as limits on fuel discharge burnup, and allow more flexible plant operation, such as relaxations in equipment technical specification requirements. The use of realistic oxidation modeling and best estimate decay power produces an even lower estimate for peak cladding temperature. Also shown in the figure are the 95% uncertainty bounds on the best estimate analysis; licensees must calculate these upper 95% bound to demonstrate that there is sufficient operating power margin relative to the regulatory limit. In addition to requests for reductions in unnecessary financial penalties, the use of best estimate analyses with characterization of the uncertainties, has been successfully used (in conjunction to changes in plant equipment), to justify higher operating powers, without violating regulatory limits (see NRC, 2020b).

This regulatory approach allows for reduction of unnecessary regulatory burden associated with overly conservative computational approaches. Although this approach requires well validated models and codes as well as additional computational effort to demonstrate regulatory compliance, it can be well worth the effort in terms of cost verses benefit. While this example was specific

Fig. 1 Illustrative example of peak clad temperature analysis for LOCA using Appendix K conservative prescriptive methods, more realistic analysis and best estimate analysis with quantified uncertainty bands. R.O. Gauntt, Gauntt Technical Safety Associates, LLC.

to demonstrating the success criteria for ECCS performance, an informed approach using best estimate analyses with characterization of uncertainty is general and can be applied to many other licensing analyses such as evaluations of pressurized thermal shock to a reactor pressure vessel (see [Pressurized Thermal Shock](#) section) or estimates for peak containment pressure during accidents.

Analyses required to demonstrate safe operation

The remainder of this article discusses analyses performed in each of the three event categories cited above, beginning with normal operations and transient upsets to normal operations that must demonstrate safe operation within the technical specifications of the reactor fuel, core and any primary or secondary side cooling systems.

Normal operations and anticipated operational occurrences (AOOs)

During normal operation, anticipated operational occurrences (AOOs) are expected to be encountered many times over the plant lifetime. The operating nuclear power plant is comprised of a great many connected and interacting systems, which include the reactor core where heat is generated, control rods to raise or lower the reactor power, the coolant pumps that move the heat to turbines or waste heat rejection systems, safety relief valves to prevent over-pressure events as well as countless numbers of valves and piping. These systems and components interact as the system operates such that, for example, a reduction in electrical load of the power grid requires that the reactor systems respond by inserting control rods to reduce reactor power to match the reduced load on the electrical generation system and restore the overall power and flow equilibrium of the plant. Failure to maintain this operational balance could result in system parameters, such as reactor coolant system pressure, exceeding vessel safety limits leading to an automatic shutdown of the nuclear reactor and plant. Such events that upset the normal balance of the plant systems are called “transients” because they upset the normal steady equilibrium of the plant. It is required to demonstrate that the plant can be safely brought to safe shutdown or operational equilibrium through operator actions or the functioning of either active or passive safety systems. The USNRC Reg. Guide 1.70 ([NRC, 1978](#)) describes many such events and scenarios that must be addressed through analyses and documented in the SAR for the plant in the licensing approval process. The IAEA provides equivalent guidance in their Safety Standards series, such as IAEA SSG-2 ([IAEA, 2009](#)). Some of the scenarios include transient situations such as:

- Increase or decrease in heat removal from the reactor coolant system
- Increase or decrease in reactor coolant systems flow
- Core reactivity or power distribution anomalies
- Increase or decrease in reactor coolant inventory
- Radioactivity releases from plant subsystems, and
- Anticipated transients with failure to (or without) scram.

These potential system states could arise by different possible initiators, leading to the same system transient. For example, a decrease in heat removal from the reactor coolant system could arise from a decrease in coolant flow rate due to a pump failure or from a loss of heat rejection to a waste heat rejection system clogged by infestation of aquatic species such as mussels. This loss of heat removal would cause the reactor coolant system pressure to rise, potentially opening safety relief valves resulting in coolant loss. Analyses of such events make use of computer models of the reactor system that treat the thermal hydraulics of the reactor coolant system (RCS) and may be coupled with physics codes that model the nuclear response of the reactor core to changes in the plant state. The code analyses predict the transient response of the reactor and plant to the accident. These analyses are required to demonstrate that system stability and equilibrium can be restored while avoiding damage to the fuel or release of radioactivity above regulatory limits and that plant operational parameters such as power levels, coolant temperatures and system pressures remain within the design technical specifications. As mentioned earlier, these requirements are referred to as “success criteria” and can be expressed quantitatively in terms of limits on peak fuel cladding temperature or radioactivity dose limits at the site boundary. In the SAR, these safety analyses must also address the extent to which critical safety systems, engineered safety systems, or operator actions must occur in meeting the success criteria as well as a required consideration of a single failure of any given safety grade system, called the “single failure criterion” described in NRC Reg. Guide 1.53 ([NRC, 1973](#)) and SECY-77-0439 ([NRC, 1977](#)).

Discussed up to now are events and deviations from full power operation; however, over the course of a fuel cycle period of from between 1 and 1.5 years between refueling, the plant can be in a range of different operating states (full power operation, low power operation, startup, cold or hot shutdown or refueling, [NRC \(2012a,b\)](#)). The operational states present different conditions for performance analyses as the decay power may be at a very low level during cold shutdown and during refueling, the reactor pressure vessel may be open to the containment, and the containment itself may be open to the environment with various safety systems that are normally operative at full power but temporarily disabled to allow refueling. These various operational states must be considered in assessing safety of normal operations and meeting regulatory dose limit requirements.

Design basis accidents

The next class of accidents to be discussed fall into a less frequent category, one that might (or might not) occur over the course of the plant lifetime but are nevertheless accommodated in the design of the plant. These accidents are called Design Basis Accidents

(DBAs). A DBA is one that presents a significant challenge to the fuel integrity, usually following a temporary loss of cooling water level in the reactor core, that may result in limited fuel damage and limited release of radioactivity to the containment building, but one for which the plant safety systems are designed to accommodate without violating any of the regulatory requirements concerning radiological releases to the environment. The concept of the DBA came out of the early days of assessing potential risks from reactor accidents in which a significant radioactive release might occur and the accident in question was termed the MCA to note that anything more extreme might be dismissed as non-credible.

In WASH-740 (AEC, 1957), it was realized that if the reactor lost the flow or inventory of coolant such that the core could melt owing to the residual decay energy from fission products, releasing radioactivity to the containment and potentially to the environment. This led to the designation of a Loss of Coolant Accident (LOCA) as a realizable credible accident that should be considered in the design capability of the plant. The limiting example of such an accident was designated to be a double ended break of the largest primary system piping, called a Large Break LOCA (LB-LOCA). It was determined eventually that the LB-LOCA accident should be one that is accommodated within the design basis of the plant, requiring such safety components as fast acting high volume flow “accumulator systems” for pressurized water reactors (PWRs) or rapid startup high volume coolant injection pumps for boiling water reactors (BWRs) found in the turbine driven High Pressure Coolant Injection (HPCI) system to quickly inject large amounts of coolant into the reactor coolant system and mitigate uncovering of the reactor core during a large coolant pipe break accident. Based on GDC requirements described in the Appendix A of 10CFR50, the design basis of the plant should ensure that the fuel remain coolable (i.e., in essentially rod-like and non-debris geometry). As noted in **Conservative versus Best Estimate and Uncertainty** section, 10CFR50.46 (U.S. Government Publishing Office, 2019) defines success criteria for LOCA safety system response, including the need to ensure peak fuel cladding temperatures remain below a maximum value of 1204 °C (2200 °F) and that local cladding oxidation be less than 17%.

Experimental evidence from the Loss of Flow Test (LOFT) and Semiscale facilities at Idaho National Laboratory (Walker, 1992) showed that under LOCA conditions with actuation of pressurized core reflooding systems called accumulators, fuel rod geometry could be maintained, and the core could be adequately cooled. As described by Martin (2021), the 10CFR50.46 success criteria must be demonstrated analytically with qualified computer codes with some inclusion of thermal margins between calculated peak clad temperatures and the 1204 °C (2200 °F) limit to account for uncertainties. In addition to demonstrating safety margin with respect to peak clad temperatures, it was also necessary to consider the environmental loads of the containment system due to sudden containment pressurization and heating from the pipe break itself as well as the potential impact of radiation and high temperature steam released to the containment on other safety systems such as safety relief valves and electronic systems that are also key to maintaining integrity of plant systems. These are all success criteria that must be analytically demonstrated in the SAR safety analyses.

Two landmark probabilistic safety studies of nuclear power plants were established with WASH-1400 and NUREG-1150 (Rasmussen, 1975; NRC, 1990). As discussed in Fleming (2021), both WASH-1400 and the later NUREG-1150 showed that small break LOCAs could also constitute significant challenges to 10CFR50.46 cladding performance criteria and Appendix A GDC. Typically, a plant SAR will consider small and large break LOCAs in the DBA realm of analyses. It is important to note that meeting all the regulatory requirements of the DBA, such as peak clad temperature or containment performance effectiveness, does not imply that the plant is not damaged by the accident or that the reactor is not a complete financial loss—only that the regulatory requirements for fuel damage and maximum dose rate at the plant boundary are not violated.

External events and fire

The discussion up to now has focused on accidents associated with DBAs, such as large coolant piping breaks that lead to core uncovering and fuel damage. These were among the first accident initiators examined in early studies such as WASH-740 (AEC, 1957). In time, other accident classes have been identified through early PRA studies such as WASH-1400 (Rasmussen, 1975) that could arise from a series of safety system failures that ultimately produce conditions where the core cannot be cooled, arising from fires which can disable electrical systems that could prevent safe reactor shutdown, by a fault in the control rod drive system, or by disabling power to coolant pumps. Similarly, seismic events could damage reactor safety systems or containment integrity through physical damage or initiation of pipe breaks, and flooding of critical areas in the plant through internal pipe breaks from perhaps fire protection systems or auxiliary water systems. These considerations are captured in the GDC. In addition, Criterion 2 requires that designs be protected against threats from natural phenomena (storms, floods, earthquakes, etc.) and Criterion 3 requires protection against fires. Some aspects of safety analyses or simply regulatory requirements that are performed to ensure that these threats are managed within the design basis of the plant.

External events

Criterion 2 of the GDC described in Appendix A of 10CFR50 requires consideration of site-specific natural phenomena such as earthquakes, floods, and natural disasters.

Seismic challenges

Appendix S of 10CFR50 provides additional specifications relative to seismic design considerations. The seismic design basis for the plant begins with siting evaluation and consideration of the regionally specific seismic potential for the purposes of assessing

appropriateness of the site and to establish the ultimate seismic loads that the plant must be designed to accommodate. In the United States, the US Geological Survey provides geographical maps characterizing the seismic hazards across the United States as shown in Fig. 2.

Here, the most seismically active regions are indicated in red showing notably the New Madrid seismic region in the mid-western United States and the Pacific coast earthquake fault region running from Southern California extending up to Alaska. Also characterized by the hazard map are the estimated probability of exceeding a given ground acceleration that can be used to relate seismic maximum design loads to the estimated frequency of occurrence. Recall that Design Basis Events are those that may happen over the duration of the plant lifetime. The design basis for earthquakes rely on historical evidence for the largest recorded earthquakes in the region. Specific plant systems and structures in this way can be designed with sufficient robustness to survive anticipated seismic loads. In this sense, two types of design basis earthquakes are defined for regulatory purposes, the Operational Basis Earthquake (OBE) and the Safe Shutdown Earthquake (SSE). Earthquakes come in all sizes, ranging from frequent earthquakes that are barely perceptible to exceedingly rare earthquakes that can cause great damage to the plant site and regional infrastructure such as roads, buildings, or dams.

The OBE is the largest earthquake that the plant can encounter without a required shutdown for damage inspection. The plant is designed to operate continuously without shutdown if the earthquake is below the OBE. On the other hand, the SSE defines the seismic loads that the plant must be designed to withstand while still maintaining safe shutdown capability and preventing any damages that result in radiological releases outside of 10CFR50 and 10CFR100 dose limits. Earthquakes larger than the SSE are outside of the plant seismic design basis and are expected to be exceedingly rare (i.e., below 10^{-5} to 10^{-6} per year). Although the SSE is larger than the OBE, it is possible to spend greater effort meeting OBE design requirements than SSE design requirements if the magnitude of the OBE is set too high relative to the SSE. Appendix S of 10CFR50 allows that the OBE can be set to a value of 1/3 or less than the SSE, and shutdown and plant examinations are not required providing the earthquake is below the OBE. If the earthquake exceeds the OBE, the plant must shutdown and perform plant examinations and assessments before restarting. Problematic is that there is considerably uncertainty associated with the frequency of occurrence of very large earthquakes, owing to their rare occurrence; and revisions to the seismic hazards characterizations have a tendency to increase in frequency estimation, potentially causing plant licensing concerns and backfitting if the margins between plant design and the latest hazards-frequency curves are too low. The seismic design of the plant includes estimating the design basis seismic loads and performing structural and vibrational analyses of key plant safety components and the secondary effects of pipe breaks and structural damage.

Flooding challenges

Similar to the seismic design basis, flooding caused by events external to the plant such as heavy rain, river flooding, and dam breaks, are defined based on maximum observed events historically or upon probabilistic models considering historical data and estimated seismic frequency distribution functions (NRC, 2011, NUREG/CR 7046), and similar GDC requirements for plant survivability of key safety systems and components are also found under 10CFR50 Appendix A, GDC Criterion 2. As with seismic hazard analyses, the analyses consider the impact of damage to plant systems in flooded areas and the impact of such damage on the

Fig. 2 2018 Long-term national seismic hazard map US Geological Survey. USGS (2018) Available at: <https://www.usgs.gov/media/images/2018-long-term-national-seismic-hazard-map>

performance of systems located outside of directly flooded areas (e.g., loss of electrical switch gear from flooding that prevents operation of safety systems located elsewhere).

In 2011, extreme flooding threats occurred at the Fukushima Daiichi nuclear power station in Japan and at the Fort Calhoun nuclear plant in Nebraska (see Fig. 3). The beyond design basis tsunami flooding accident at Fukushima Daiichi resulted in fuel melting and containment failures at the Unit 1, 2 and 3 reactors with significant offsite releases (see Mizokami and Rempe, 2021); whereas the flooding of the Missouri river at Fort Calhoun was anticipated for days prior to the event and inflatable dykes were placed around the reactor site to prevent flooding of the plant (New York Times, 2011). In 2019, the Missouri river flooded again, threatening the plant where mitigating measures were taken to avoid plant damage. As with seismic threats, contemporary estimates of flooding potential at nuclear power plants can increase with passage of time owing to climate change and rising sea levels. In the case of the tsunami flooding of the Fukushima Daiichi site, the original estimates of maximum tsunami potential were found to underestimate the observed event where the 14-m tsunami height surpassed the site protective sea wall by more than 6 m. These examples illustrate the importance of careful consideration of rare events such as tsunami flooding, or more frequent than anticipated extreme seasonal flooding events such as the Fort Calhoun incidents (Fig. 3).

Fires

Unlike rare tsunami flooding events or infrequent river flooding events, fires are common events in industry, requiring fire protection programs to anticipate and mitigate their severity and consequences. A significant fire occurred at the Browns Ferry Nuclear Power Station that threatened the safety of the plant and had profound effects on the nuclear industry with respect to fire protection (NRC, 1993; Rempe, 2021b). The regulatory oversight of fire safety prior to the Browns Ferry fire in 1979 was addressed by GDC Criterion 3, requiring that the high-level objectives: *Structures, systems, and components important to safety shall be designed and located to minimize, consistent with other safety requirements, the probability and effect of fires and explosions. Noncombustible and heat-resistant materials shall be used wherever practical throughout the unit, particularly in such locations as the containment and control room.*

Again, the GDC of Appendix A of 10CFR50 require that fires be addressed within a design. Criterion 3 is focused on fires and requires consideration of potential sources of fire initiation, protection measures such as managing sources of combustible materials and consideration of the damage to critical safety systems and components that might threaten safe operation of the plant and safety systems. General industry-wide fire safety practices are applied, such as minimizing combustibles in fire-sensitive regions of the plant where electrical cables or safety critical components reside and inspections. The potential for unintended damage caused by fire suppression systems is also considered in terms of water causing electrical shorts or damaging equipment and effects of smoke.

The Browns Ferry fire was a serious challenge to the aims set forth in GDC 3; a fire was initiated due an inspection of cable pass-through insulation by a procedure involving a lit candle to detect air leakage. The lit candle ignited the insulating material which resisted efforts to extinguish owing to the organic nature of the polyurethane insulating material and the high temperature of the burning insulation. Water was initially avoided due to fears of electrical shorts but was eventually used to extinguish the fire after other fire suppression measures failed but not before serious damage to some of the cables relied upon for shutdown cooling.

Following this fire, the USNRC set up additional prescriptive requirements that were codified in Appendix R of 10CFR50 in 1981. These requirements were aimed at meeting Criterion 3 objectives but also included specific prescriptive measures that plants must meet such as: fire protection programs and inspections; fire hazards analysis demonstrating that a serious fire which disables

(B)

Fig. 3 Important Flooding Events at Fort Calhoun power station and Fukushima Daiichi Nuclear Power Plant in 2011. (Right) Flooding of Missouri River at Fort Calhoun Nuclear Power Station; (Left) Fukushima tsunami flooding. From (A) New York Times (2011) *Flooding Brings Worries Over Two Nuclear Plants*. Available at: <https://www.nytimes.com/2011/06/21/us/21flood.html?searchResultPosition=1> (accessed June 20, 2011); (B) TEPCO (2011) Available at: <https://photo.tepco.co.jp/en/date/2011/201105-e/110519-02e.html>

one train of shutdown and cooling capability will leave another protected and redundant train available; specifications on fire barrier duration times; and detailed and prescriptive requirements on training, drills, and administrative procedures. So-called deterministic analysis of fires and their potential consequences could be used to, for example, show that if a fire destroys an entire room that there remains an alternative success path to achieving Criterion 3 objectives.

Appendix R requirements are still used today for many plants, although more “risk informed” practices are allowed that focus on performance-based requirements and probabilistic considerations. Currently, fire regulation is based on NFPA 805, the fire standard developed by the National Fire Protection Association. The NFPA 805 standard offers performance-based requirements which can best be demonstrated through a Probabilistic Risk Assessment (PRA) of the spectrum of fire threats. The fire PRA, similar to the severe accident PRA, is a systematic and somewhat exhaustive analysis of the detailed and interacting systems that come into play during a fire such as co-located systems, common mode failure issues, impact on unrelated safety systems, fire intensity and duration, performance of fire barriers, all considered in an event tree/fault tree analysis construct. This type of risk-informed approach can identify which systems are key to meeting GDC 3 and NFPA 805 objectives and prioritize where resources are aimed, potentially increasing safety and reducing maintenance costs. The cost of performing a fire PRA is substantial; and although it is the current state of art in fire safety and consequence assessment, not all plants embark on the NFPA 804 PRA approach. Plants originally licensed under Appendix R (or earlier) requirements are not obligated to adopt NFPA 805 standards and practices but may be required for certain license amendments. As noted in [Dube \(2021\)](#), it has been implemented in about half of the US plant sites (as of 2019).

Additional considerations

Several additional considerations, that are important elements of modern safety analyses, were added to the regulatory framework to accommodate gained operational experience. Three will be discussed here: Pressurized Thermal Shock, Station Blackout and ATWS.

Pressurized thermal shock

Licensees are now required to perform analyses demonstrating adequate protection of the reactor pressure vessel, which is a major element in the reactor’s layers of defense in depth ([NRC, 1993, 2015](#)). This requirement was imposed after a phenomenon known as “Pressurized Thermal Shock (PTS)” was observed in a non-nuclear pressure vessel due to cold water coming into sudden contact with a hot pressure vessel wall. The cold water generated thermally induced stresses that fractured the vessel wall, resulting in a catastrophic failure of the pressure vessel. In this scenario, the cooled vessel wall becomes brittle and subject to fracture under the high tensile stresses at the vessel wall inner surface. It was recognized that in nuclear reactor pressure vessels, radiation damage by neutrons on the inner pressure vessel wall can reduce the ductile-to-brittle transition temperature. Over decades, radiation damage to the vessel wall can increase the likelihood of PTS. This realization led to the so-called Pressurized Thermal Shock Rule, an added requirement from the codified 10CFR50 and 10CFR100 legislation ([NRC, 1993, 2015](#)). Computational methods, backed up with samples of irradiated pressure vessel wall materials to measure the reduced ductility, are now required to evaluate PTS. The aim of the analyses is to demonstrate adequate margins from catastrophic vessel failure arising from anticipated transient overcooling events. Evaluations include principally detailed transient thermal analysis of overcooling vessel wall events to determine the peak vessel wall stress levels and use of fracture mechanics analysis to demonstrate acceptably low frequency of catastrophic fractures. If margins to failure are low, possible remedies include decreased operating power to reduce neutron damage, vessel annealing, or even vessel replacement.

Station Blackout

Another such after-construction regulatory accommodation relates to the vulnerability of safe plant operations to the loss of offsite and onsite electrical power referred to as Station Blackout. First recognized in the WASH-1400 probabilistic risk study ([Rasmussen, 1975](#)) and later quantified in terms of frequency of occurrence in the NUREG-1150 study ([NRC, 1990](#)), it was found that roughly 50% of the core damage frequency (CDF) for many existing power plants was due to Station Blackout, a risk profile not appreciated until modern PRA methods were available to root out such vulnerabilities. Essentially, the SBO rule requires that power plants be capable of maintaining adequate core cooling and containment integrity during SBO for a plant-specific duration of time generally between 2 and 16 h, often determined by on-site DC battery capacity. This duration is referred to as the “coping time” for SBO in which appropriate mitigations can be implemented to prevent plant damage. However, if mitigations cannot be implemented within the plant-specific coping time, long term loss of reactor cooling and heat rejection can lead to core damage, and severe accident systems analysis computer codes such as MELCOR ([Humphries, 2015](#)) and MAAP ([EPRI, 2015](#)) can be used to evaluate core damage and radiological releases. Aspects of plant systems affecting the success of this strategy include ensuring high reliability of onsite diesel-powered AC power and system redundancy. This requirement received additional scrutiny following the 2011 accidents at the Fukushima Daiichi power plant, where extended loss of AC power (ELAP) persisted well beyond 8 h leading to three sequential core melting events (see [Mizokami and Rempe, 2021](#)).

Anticipated transient without SCRAM (ATWS)

Prior to 1969, the accident mode commonly referred to as ATWS was not well appreciated and not generally considered in safety analyses ([NRC, 1993](#)). While much of the topic concerning transient analyses is in the realm of design basis accidents—that is those

accidents we have anticipated and accommodated by design features in the plant, an additional system failure to scram the reactor was not originally considered. One such anticipated transient is a loss of feed water transient in which loss or decrease in feedwater to the steam generators of a PWR would call for an automatic scram of the reactor while safety systems engage to address the problem. Not considered in this event, however, would be a failure to scram the reactor. Such an event was generally thought to be extremely unlikely and on the order of 10^{-7} per year in frequency. In February 1969, a consultant to the ACRS, E.P. Epler, made the observation that if anticipated transients were estimated at a frequency of something on the order of one per year and that failure to scram might be a 10^{-4} event based on reliability analyses, then the ATWS scenario might be more on the order of 10^{-4} per reactor year and not 10^{-7} per year, putting the NRC on a course for rulemaking on the issue (NRC, 1993). A controversial report, WASH-1270 (1973) explored how to accommodate protection from ATWS with some consideration given to whether the plant was easily modified to accommodate ATWS or whether an older plant was not so easily modified. The final ATWS Rule placed additional requirements on the independence and diversity of shutdown capability. However, before rulemaking could be completed, two real world events at the Browns Ferry BWR plant (1980) and the Salem PWR plant, occurring in 1980 and 1983, respectively. In the Browns Ferry event, a shutdown from low power suffered a failure of the control blades to insert on one side of the reactor that was found to be due to a hydraulic problem with the blade insertion system (see Lutz and Williamson, 2021b). In the Salem events, an electrical problem prevented scram for an automatically generated shutdown due to low steam generator water levels (see Lutz and Williamson, 2021b; Rempe, 2021b). Although these incidents had no ultimate safety impact (perhaps because the reactors were at very low power), they highlighted the frequency significance of ATWS events and led to greater industry focus on reducing the frequency of reactor scram at full power. Due to improvements in reactor protection systems between 1980 and 1995, the frequency of scram in the US fleet was reduced by about a factor of 10 and at-power scrams today are extremely infrequent. This of course reduced the overall frequency of ATWS by at least this factor, but interestingly brought great savings to the industry by reducing the lost revenue due to undesired scrams (NUREG/CR-6042 Rev. 2).

Severe accidents beyond the plant design basis

As discussed earlier, potential health effects of severe accidents were explored in landmark studies such as WASH-740 (AEC, 1957) and WASH-1400 (Rasmussen, 1975) based on postulated maximum credible events that could result in radioactive releases from a damaged or melted reactor core which could subsequently escape from the containment and threaten public health. In NUREG-1150 (NRC, 1990), probabilistic risk assessments were performed for five US BWR and PWR power plants, focusing in what are called “internal events,” in which a spectrum of accident sequences and outcomes are explored based on fault-tree/event-tree analyses of the “things that can go wrong internal to the plant.” Briefly, internal events reflect the spectrum of pipe breaks (considering their sizes and locations), Station Blackout scenarios with loss of power or loss of heat rejection, and many other accidents with nuanced variations. In the PRA, thousands of scenarios are examined probabilistically. In most cases, core damage or radiological releases are arrested by the successful activation of safety systems. However, in some cases in which core melting occurs with subsequent release of radioactivity to the containment followed by containment failure, releases or radioactivity to the environment with potential health consequences can occur.

One of the metrics adopted in the NUREG-1150 study was called the “conditional containment failure probability” (CCFP), which is the probability for a given plant that the containment ultimately fails conditional on a core melting accident having taken place. While the “core melt frequency” determined in the PRA is generally a low frequency event on the order of 10^{-4} per reactor year or lower, the CCFP for the NUREG-1150 plants generally ranged between 0.1 and 1.0. This ultimate containment failure was further characterized as an early containment failure or late containment failure depending on whether the radiological release would take place before or after protective measures such as evacuations or shelter in place could be implemented. Accidents of this magnitude have the potential to significantly exceed the regulatory requirements of 10CFR50 concerning core coolability and 10CFR100 concerning radiological dose to the public. Such accidents are deemed in the US regulatory framework as being beyond the plant design basis, or Beyond Design Basis Accidents (BDBAs) as happened in 2011 at the Fukushima Daiichi plant. Typically, such severe accidents require the failure of multiple safety system failures such as failure of the ECCS to effectively reflood and cool the core following a DBA LOCA, for ELAP conditions to persist beyond the plant-specific coping time, or any number of other system failures that push the accidents outside of the plant design basis.

In the United States, there are no specific success criteria for BDBAs other than a regulatory requirement imposed by the NRC following the accident at Three Mile Island requiring plants to perform a PRA or an industry version of a PRA, known as an Individual Plant Examination (IPE), and include the PRA findings in an added Chapter 19 to the plant SAR (US NRC, 1988). The idea was to encourage licensees to assess potential plant vulnerabilities and make cost effective plant modifications that would reduce specific vulnerabilities or improve the overall plant core damage frequency (CDF), without placing onerous backfit requirements on the plant owner/operator. In meeting these requirements, plants must perform at least a Level 1 PRA (or IPE) to identify the plant sequences that lead to core damage events, although the plants can optionally perform a full scope PRA that includes a Level 2 analysis that further determines the radiological source terms resulting from core damage accidents and a Level 3 analysis that estimates the health effects from offsite radiological releases (see Modarres and Kim, 2021). Radiological consequences are expressed in terms of potential prompt fatalities from large and early releases mainly associated with Iodine releases or longer-term latent health effects such as cancers and lymphomas due to chronic exposure to low level radiation, such as from Cs-137/Cs-134 land contamination. The Level 1 analysis codes model the plant accident from its initiation up to the point of fuel damage that exceeds the 10CFR50.46 temperature and cladding oxidation limits and are aimed mainly at defending the DBA success criteria for fuel performance and core

coolability. Those accidents that fail the 10CFR50.46 success criteria and proceed to core melting accidents are deemed beyond the design basis in the US (BDBA) with radiological releases. Another class of Severe Accident Analysis computer codes is used to predict plant state responses, such as fraction of core damaged or melted, rate and timing of radiological releases, generation of hydrogen and its behavior in the containment, and the containment response to increasing pressure and temperatures that can lead to offsite releases. The Level 3 consequence and health effects use the radiological source term information from the Level 2 analyses together with the site weather characteristics as boundary conditions to an atmospheric transport code which calculates the downwind atmospheric transport of radioactive releases and the fallout to the ground to estimate ground contamination and near or long term health effects on humans.

Post 9/11 measures and Fukushima lessons learned

Following the September 2001 attacks on the World Trade Center in which commercial aircraft were used to destroy two towers, an urgent study was initiated by the NRC to explore the vulnerabilities of nuclear power plants to commercial aircraft attack. The scenarios examined considered the loss of large areas of the plant due to the damage from an aircraft impact, but in many ways resemble Station Blackout conditions ELAP and resultant loss of decay heat removal to move heat via pumps as well as loss of cooling function from large area damage. The studies showed that on-site availability of alternative means of generating AC power with portable generators and on-site availability of portable pumps could be highly effective in mitigating the ELAP conditions. This finding led to the NRC requirements of plants maintaining portable emergency equipment, such as generators and pumps, to mitigate such events.

Also identified in the aircraft impact studies was the vulnerability of spent fuel pools of certain plant designs that are outside of the containment and more vulnerable to aircraft attack—here a sudden loss of water from the spent fuel pool could result in damage to spent fuel from a sudden loss of cooling water. Until this time, there were no guidelines on the loading and distribution of off-loaded fuel in the spent fuel pools. However, research showed that optimal fuel dispersing practices in which very hot, recently off-loaded, fuel was interspersed among colder, earlier-offloaded, fuel assemblies could significantly reduce the likelihood of a severe spent fuel pool accident. Optimal fuel distribution guidance was developed, and the NRC Commission issued orders requiring that the US fleet adopt such optimized storage practices.

A decade later, the accidents at the Fukushima Daiichi plant reinforced the need to maintain portable equipment to respond to loss of large area, this time from natural disasters as opposed to terrorist initiators. This further reinforced the industry commitment to maintaining portable equipment and ensuring that logistical concerns, such as length of hoses, compatibility of hose connections, and the time required to implement mitigation measures were addressed. Both the 9/11 (2001) terrorist events and the 3/11 (2011) Fukushima accidents have led to increased DiD and mitigation options for extreme plant damage scenarios.

Emerging issues

New reactor designs under consideration include non-LWR concepts, many of which may be small modular designs because of their potential to increase safety and decrease manufacturing and construction costs. The current generation of LWRs is based on decades of cautious research into a developing nuclear technology. The research base in non-LWR concepts, which include novel designs using molten salts or liquid metals as working fluids and new fuel forms from the UO₂ fuel used for decades in the LWR industry, will require development of new regulatory guidelines. Development timelines for these advanced reactors cannot afford the decades invested in the regulatory oversight and research that the LWR industry enjoys. Advanced analysis methods are being developed to demonstrate safety in the design of the next generation nuclear power concepts, and validation of these methods will be critical in advancing the strategic impact of nuclear power in an ever more dangerous world to address climate change and the need for safe and secure power. As with LWRs, advanced analytical methods must meet regulatory requirements to satisfy health and safety objectives and high level design requirements.

Summary

The safety analysis of commercial light water nuclear power plants has been under continuous evolution and improvements since the first reactors were constructed in the 1950s. Practical and operational experience has been gained over the years from knowledge advancements, experimental investigations, and several landmark real-world accidents. Regulatory practice is reflected within the rules and guidance's set forth in Regulatory Guides and Safety Standards by the NRC, IAEA, and other international oversight agencies. The analyses described in this article are aimed at assuring safe nuclear shutdown capability and core cooling capability under all possible accident conditions including normal operations, anticipated transients, design basis accidents, and the minimization of risks from severe accidents that are outside the design basis of the plant. This article has provided an overview of the types of safety analyses required to demonstrate design safety and approval for operations with the principal objective of maintaining adequate health and safety to the population. In addition, this article identified what guidance is available for performing these analyses, and what criteria are compared with analyses results.

Glossary

Defense-in-Depth A design and regulatory principle that relies on several consecutive and independent levels of protection that would have to fail before harmful effects could be caused to people or to the environment. If one level of protection or engineered barrier were to fail, the subsequent level or barrier would be available. When properly implemented, Defense-in-Depth ensures no single technical, human or organizational failure could lead to harmful effects and the combinations of failures leading to significant harmful effects are of very low probability.

Graded approach to regulation An approach in which the level of regulatory oversight is balanced against the hazard potential of the nuclear installation; i.e., the greater the hazard potential of the installation and hence the complexity of the engineered barriers to maintain the safe working envelope, the greater the regulatory requirements and depth of safety assessment, regulatory inspection, and enforcement powers.

Inspection The core activity performed by the regulator to verify compliance with its regulatory requirements, including regulations, license conditions and permits.

Nuclear facilities and activities Facilities and activities that may result in radiation risks arising from the use of nuclear or radioactive materials.

Nuclear materials Plutonium, uranium 233, uranium enriched in the isotopes 233 or 235, and any material containing one or more of the foregoing. Nuclear material does not include source material (i.e., uranium containing the mixture of uranium isotopes contained in nature; uranium depleted in the isotope 235; thorium; or any of the foregoing in the form of metal, alloy, chemical compound or concentrate) (Adapted from IAEA, 1980).

Nuclear regulation The inspection, assessment, permissioning and enforcement activities necessary to control the siting, design, construction, commissioning, operation and decommissioning of nuclear installations.

Nuclear safety All the activities required to be undertaken to protect workers, the public and the environment from the effects of ionizing radiation as a consequence of operating nuclear facilities during both normal and accident conditions.

Nuclear security All the activities required to be undertaken to prevent the theft of and illegal transfer of nuclear or radioactive materials and to prevent unauthorized access to or sabotage of nuclear facilities.

Regulatory capture Process in which a regulatory agency becomes dominated by the commercial or political concerns of the industry or sector it is charged with regulating. Eventually a captured public-interest agency operates essentially as an advocate for the industries it regulates. Such cases may not be directly corrupt, as there is no quid pro quo; rather, the regulators simply begin thinking like the industries they regulate.

Safety analysis The study of the behavior of a nuclear installation under both normal operation and postulated accident conditions in order to determine: (a) safety margins provided in normal operation and in transient conditions, and (b) the adequacy of the engineered barriers needed to detect the departure from normal operating conditions and initiate protection systems to prevent or limit the consequences of accidents.

Safety assessment Carried out by the regulator, the systematic and independent evaluation of the safety analysis set out in a safety case for a nuclear installation. It is used to enable the regulator to judge the adequacy of the licensee's safety case and support licensing decisions on the plant acceptability, once the risk associated with its operation is known.

Safety culture Culture that encourages a questioning and learning attitude and discourages complacency with regard to safety.

Introduction

Society demands that industrial applications having the potential to cause harm to people or the environment should be subject to regulation by their Government. The amount of regulatory oversight is dependent upon the scale of the potential hazard. The use of nuclear energy is no exception; and hence, because of its high hazard potential, it is subject to a stringent nuclear regulatory framework. It is the Government's responsibility to make the laws that establish the nuclear regulatory framework. The nuclear operators/licensees have a responsibility to comply with the legal requirements set out in the regulatory framework, and it is the role of the regulators to enforce the law. Nuclear regulation is, therefore, essentially law enforcement.

There is no universal legal system that governs nuclear safety. Hence, the responsibility for establishing a nuclear regulatory framework rests with each Nation State. As nuclear regulation is an integral part of a Nation State's legal system, there is no single template for nuclear regulation and licensing. However, Member States of the United Nations International Atomic Energy Agency (IAEA) have developed a number of international conventions in the area of nuclear safety and nuclear security in order to provide the international community with the necessary confidence that nuclear safety and nuclear security is being delivered to consistent standards. The key conventions are the Nuclear Safety Convention (IAEA, 1994), the Joint Convention on the Safety of Spent Fuel Management and on the Safety of Radioactive Waste Management (IAEA, 1997), and the Convention on the Physical Protection of Nuclear Materials (IAEA, 1980, 2011, 2016).

To support these Conventions, the IAEA has produced extensive guidance on nuclear law (Stoiber et al., 2003) and established a comprehensive set of nuclear safety standards and guides. The IAEA safety standards, principles, and guidance are intended for use by Member States, national authorities, and other international organizations. The Fundamental Safety Principles (IAEA, 2006) provide the high-level aims that are necessary for Member States wishing to make use of nuclear energy. These principles define the roles and responsibilities of the licensee, the regulator, and the government. They also address the need to consider topics, such as justification of facilities and activities that give rise to radiation risk, balancing the optimization of protection with individual risk limitations, the protection of both current and future generations, and prevention and mitigation of accidents. These principles provide a basis for Member States to establish safety requirements for protection against exposure to ionizing radiation under the IAEA's safety standards program and provide the rationale for its wider safety related program. However, the application and enforcement of such standards remain a national obligation.

The nuclear safety conventions and their associated standards clearly place the responsibility for safety on the operator/licensee of the facility. In the case of nuclear security, responsibility is placed on the Government of the Member State. However, the consistent theme of the international nuclear safety and nuclear security framework is the protection of people and the environment from the harmful effects of ionizing radiation. Hence, most regulators indicate their primary mission or safety objective is the protection of people and the environment. Regulators provide assurance to their Governments that nuclear energy is being used safely and securely and in accordance with the legal requirements.

Although it is recognized that nuclear regulation is, in general, a national responsibility, Governments have long recognized the transboundary risks associated with the release of radioactive materials into the environment. The accidents of Three Mile Island (Skillman and Rempe, 2021), Chernobyl (Sich, 2021), and Fukushima Daiichi (Mizokami and Rempe, 2021), reinforced the benefits of improved international policy coordination (Lamm, 2017). The IAEA has played a significant role in the development of international safety standards covering such things as: Government responsibilities to establish a regulatory framework; the siting, design, construction, commissioning, operation and decommissioning of nuclear facilities; the transport of nuclear materials; and the management of radioactive waste. The IAEA has also established programs to assist countries in the evaluation of the effectiveness of their regulation of nuclear facilities and activities. In addition to the IAEA, the Nuclear Energy Agency (NEA) of the Organization of Economic Cooperation and Development (OECD) plays a role in providing guidance on nuclear safety and regulation

in order to share good international and national practice with regulators and the nuclear operating organizations. In the area of nuclear security, the World Institute for Nuclear Security (WINS) provides a forum for promoting best practice.

This chapter provides an overview of nuclear safety regulation and regulatory frameworks. More detailed information, with specific examples, is found in [Bley and Malsch \(2021a,b\)](#), [Ray \(2021\)](#), [Rempe \(2021\)](#), and [Williams \(2021\)](#). Because of the early role the U.S. played in the deployment of nuclear technologies for non-military applications, the U.S. experience is emphasized in these chapters. The focus of this chapter is on the regulation of nuclear facilities for commercial power applications. Hence, statements do not apply to the limited number of research and nuclear fuel cycle facilities located on government sites in some countries. Within the U.S., these research and fuel cycle facilities are subject to internal regulatory oversight by the U.S. Department of Energy. Whilst some countries have followed the U.S. approach, other countries such as the United Kingdom developed different regulatory approaches. These are discussed in [Williams \(2021\)](#).

Safety objective and scope

Internationally, the primary mission or safety objective of nuclear regulatory organizations (often called the Regulatory Body) is the protection of people and the environment from the harmful effects associated with the use of radioactive materials (e.g., [US NRC, 2018](#); [IAEA, 2006](#); [OECD, 2014](#)). Regulators operate within the powers granted to them in a Nation's nuclear laws, which often require an operator of a nuclear installation to be licensed. Regulators aim to achieve this objective via the application of a licensing process that may include conditions attached to a License and the application of Regulations. The licensing process often imposes measures to enable the Regulatory Body to be assured of the following: nuclear facilities are sited, designed, constructed, commissioned, operated, and decommissioned to the appropriate safety standards; radioactive waste is effectively managed; and the risks to workers and the public are as low as reasonably achievable (ALARA). In some countries, risks are required to be as low as reasonably practicable (ALARP). As discussed in [Risk justification and assessment](#), the concepts of ALARA and ALARP differ but are typically assumed to have equivalence.

As noted in [IAEA \(2006\)](#), the regulatory process has the following objectives:

- controlling radiation exposure of people and release of radioactive material to the environment;
- restricting the likelihood of events that might lead to a loss of control over a nuclear reactor core, nuclear chain reaction, and radioactive source or any other source of radiation;
- mitigating the consequences of such events if they were to occur.

Regulation applies to all facilities and activities and for all stages of the life of such facilities including the associated transport of radioactive material and management of radioactive waste. Regulation is applied to operating facilities during normal operating conditions and off-normal events (e.g., accidents). A graded approach is applied to regulation to ensure the regulatory burden is proportionate to the hazard.

Roles

It is usual for a Regulatory Body to grant a nuclear license to construct or operate a nuclear facility to a corporate organization when it is satisfied that the organization is fit to hold a nuclear site license. The Regulatory Body can "license" particular individuals to undertake specific activities, e.g., to operate a nuclear reactor. Once the Regulatory Body has granted a license to an organization, it becomes the licensee and has the primary responsibility for safety throughout the lifetime of the facility and any associated activities.

As discussed above, regulating nuclear and radiation safety is a national responsibility. Under the Nuclear Safety Convention, Governments must establish a Regulatory Body and ensure it is effective. To be effective ([IAEA, 2006](#); [IAEA, 2010a](#)), the Government must ensure the regulator has the following attributes:

- adequate legal authority, technical and managerial competence, and human and financial resources to fulfil its responsibilities;
- effective independence from the licensee and any other body, so it is free from any undue pressure from interested parties;
- appropriate means for informing those in the vicinity (e.g., the public and other interested parties) as well as the information media about the safety aspects (including health and environmental aspects) of facilities and activities and about regulatory processes in an open and inclusive process.

In the field of nuclear safety, radiation protection and environmental protection, the Government and the Regulatory Body often share the responsibility for establishing appropriate standards and regulatory processes to achieve the primary mission and safety objective. However, the prime responsibility for safety rests with the licensee. The Regulatory Body is not responsible for safety.

In the field of nuclear security, the Regulatory Body is often referred to as the "Competent Authority"; however, it is the Government that is responsible for nuclear security. The Government and the Regulatory Body, again, often share the responsibility for establishing appropriate standards, regulations and regulatory processes to achieve the primary mission and security objective. The Government has the responsibility of defining the "Design Basis Threat," i.e., the threat against which the licensee must provide protection. Protection may include the use of an armed guard force which may be under the control of the licensee or the Government. The licensee has the responsibility for complying with the nuclear security regulations.

The Convention on Nuclear Safety emphasizes not only the operator's ultimate responsibility for safety but also the importance of an independent, technically competent regulator. (IAEA, 1994) Among the core lessons learned from the Fukushima Daiichi accident, the Director General's report (IAEA, 2015) listed several attributes characteristic of an effective regulatory framework, such as the need for an independent Regulatory Body with the necessary legal authority, technical competence, and a strong safety culture. IAEA (2015) also emphasized the importance of having a questioning attitude, continuously challenging or re-examining prevailing assumptions about nuclear safety and the implications of decisions and actions that could affect nuclear safety.

The Regulatory Body has an important role to play in the delivery of nuclear safety and nuclear security; however, the regulator is only one part of a "triple lock" needed to protect society (Williams, 2013a,b). This triple lock comprises three key components. The first lock is the technically competent licensee. The second lock is the Licensee's internal (independent of operational responsibilities) nuclear safety assurance function. The third of the three required locks is an effective Regulatory Body. When all three locks are in place, society can be confident that the use of nuclear energy is safe and secure.

Further analysis of the Fukushima Daiichi accident indicated that a network of institutions and interfaces or "Institutional Strength-in-Depth" (ISiD) is also required (INSAG, 2017; Meserve, 2016). To prevent a nuclear accident, the ISiD philosophy relies on three independent institutional sub-systems:

- a strong nuclear industry
- a capable and effective nuclear Regulatory Body
- stakeholders who reinforce and ensure a robust institutional framework

It is argued that Government should ensure each sub-system has the authority and responsibility to fulfil its clear and distinct role and should link them together so each sub-system strengthens and reinforces the others. For example, the U.S. Government, by law, establishes the obligations of the licensee, creates the Regulatory Body, and through law, governs access to information, public hearings, and legal processes for challenging the Regulatory Body (enabling the public to oversee the entire process). Meserve (2016) observes that to be effective, it is important for each sub-system to have internal ISiD that incorporates elements or layers, such as a strong technical capability, a management system with multiple checks, internal independent oversight, external expert panels, a strong quality control and assurance program, and a vibrant safety culture. Although several references (e.g., see IAEA, 2016; INSAG, 2017) emphasize that the primary responsibility for safety lies with the licensee, the Regulatory Body has the prime responsibility for oversight of the licensee. Thus, the Regulatory Body must have the authority, technical knowledge, capacity and capability to ensure the operator has robust ISiD in place and the protection of the public, society and the environment is always secured. To do this effectively, the Regulatory Body must have its own "ISiD" firmly established within its own organization. Linkages among the various sub-systems depend on transparent and open communications and accountability. Leaders in industry and the Regulatory Body must welcome challenges from stakeholders, listen, respond openly, learn, and improve. Fig. 1 depicts the ISiD model of a robust national nuclear system (INSAG, 2017).

In the U.S., a license is granted for a limited time period. Upon expiration, the licensees must apply for a new license or license renewal. As described in Ray (2021), the regulator also certifies reactor designs for a period of time within the U.S. This is a process in which the public can again provide input and the regulators can review the safety of the licensed facility. As elaborated upon in Williams (2021), licenses are valid over different time periods. In Canada, licenses are valid for 2–5 years. In the U.S., licenses are valid for 40 years, and renewals are granted for up to 20 years. In several countries, regulators use a periodic safety review

Fig. 1 Graphic depiction of a robust national nuclear system ("Regulation" is regarded as the interactions between the Regulatory Body and industry; it includes all regulatory activities and controls, but a prime method of interaction and feedback is the use of regulatory inspection activities.). Courtesy of International Nuclear Safety Advisory Group (2017) *Ensuring Robust National Nuclear Safety Systems—Institutional Strength in Depth*. INSAG-27, IAEA Publication 1779, Vienna.

(PSR) process, with a reassessment usually every 10 years. In the United Kingdom, the license is not time-limited, but each facility is required to undertake a PSR and continued operation is conditional on the Regulatory Body accepting the licensee's safety case to support its PSR. Time limitations on licenses can, depending on the national legal framework, be beneficial. For example, time limits can be used to force up-to-date best practices and periodic scrutiny of licensee performance. In addition, a licensee may be seen to be more accountable if public input is sought frequently over the lifetime of the nuclear power plant.

Regulatory functions

Typical actions conducted by an effective Regulatory Body are identified in several references (e.g., [OECD, 2014](#); [INSAG, 2017](#)) and include the following:

- define safety goals
- set policies and standards
- produce regulations
- license nuclear installations
- review licensee (or applicant) safety submissions during siting, design, construction, commissioning, operation and decommissioning
- carry out independent safety assessments
- permit licensee activities such as construction, commissioning, operation, modifications to the licensing basis, etc.
- sponsor safety research
- review operating experience
- interact with stakeholders and inform the public on radiation protection and nuclear safety
- conduct inspection activities to verify compliance with regulations or license conditions
- carry out enforcement activities such as issuing letters, notices, fines, prosecutions, and shutdown
- oversee/advise on emergency preparedness

Safety assessments and inspections

Safety assessments involve the systematic analysis of the behavior of a nuclear facility under both normal operation and accident conditions. Its aim is to substantiate the claims made in the Licensee's safety case in order to verify the necessary safety margins and the consequences of postulated accident conditions. Safety inspections are required to verify licensee compliance with regulatory requirements and commitments. The Regulatory Body does not have unlimited resources; and hence, it has to sample both the safety documentation provided by the Licensee and prioritize its inspection activities. The selection of appropriate samples to investigate and the prioritization of inspection activities are based on a combination of experience and the application of a graded approach. For those facilities with high hazard potential and complex engineered barriers needed to maintain the safe working envelope, the Regulatory Body would expect to carry out more in-depth assessment over a larger sample of the safety documentation, and prioritize its inspection activities on those aspects of the licensee's operations that maintain the integrity of the key nuclear safety and security systems.

A facility may only be constructed and commissioned, or an activity may only be commenced, once it has been demonstrated to the satisfaction of the Regulatory Body that the safety case for the design of the facility, including the proposed safety measures, is adequate. Safety assessments, in whole or in part, must be repeated as necessary throughout the lifetime of the facility in order to consider changes in circumstances (such as new standards or new scientific and technological developments), lessons learned from operating experience and accidents, modifications, and aging effects. Inspection is a continuous process commencing with construction. The Regulatory Body's inspection plans are tailored to the different phases over the lifetime of the facility.

International guidance emphasizes the importance of learning from accidents and operating experience ([INSAG, 1996](#); [OECD, 2014](#)). The licensee is expected to have processes for the feedback and analysis of operating experience, including initiating events, accident precursors, near misses, accidents and unauthorized acts, so lessons may be learned, shared, and acted upon. The Regulatory Body should monitor the Licensee's activities in these areas through its inspection plan to ensure the Licensee is taking the necessary actions and learning from experience. As discussed in [Lutz and Williamson \(2021a,b\)](#), effective emergency procedures and response actions must be comprehensive, prepared in advance, and practiced. For facility-based emergencies, the licensee is responsible for producing the necessary emergency plans and the Regulatory Body is expected to approve the plans, which normally involve annual demonstration exercises. The Regulatory Body, as part of its facility inspection plan, is expected to assess the licensee's performance during these exercises and require improvements should the Licensee fail to demonstrate its ability to successfully manage the event being tested in the exercise. In some countries, the Regulatory Body contributes to the development and testing of off-site emergency plans.

Stakeholder interactions

Public acceptance of nuclear power is not a matter for the Regulatory Body; public acceptance is a matter for Government and society. The Regulatory Body, whilst being neutral on the deployment of nuclear energy, has a role to play in enabling the public and other

stakeholders to have confidence in the safety and security of nuclear facilities (Here, the term, “stakeholders,” refers to all interested parties, including the public, non-governmental organizations, media, and shareholders. Views from stakeholder constituents may differ.). Public trust and confidence in the Regulatory Body is therefore essential; to gain and maintain this trust, the Regulatory Body must not only be independent but also be seen to be independent. The public and other key stakeholders must have trust in the people making the regulatory decisions. The Regulatory Body’s approach to inspection of nuclear facilities, its methods of assessing the nuclear safety cases, and its approach to enforcement should be transparent and be in the public domain. The Regulatory Body should produce regular reports that allow the public to see not only what the Regulatory Body has been doing, but also to see the Regulatory Body’s assessment of the licensee’s nuclear safety and security performance. Regular presentations to the media and public hearings to explain the actions of the Regulatory Body also contribute to the development of this trust.

Several publications emphasize the important role of stakeholders. As observed in (INSAG, 2006), the nuclear industry and the Regulatory Body have an obligation to explain nuclear safety provisions and plant performance in an open, comprehensible and transparent way and to respond to legitimate questions and challenges.

The Regulatory Body should develop and maintain its relationships with key stakeholders throughout the lifetime of the facility from the initial siting of a facility through construction, commissioning, operation and decommissioning. In many countries, the siting of a nuclear facility is the responsibility of either central or regional Government and controlled via planning legislation. The Regulatory Body is often required to provide information on the nuclear regulatory system at planning inquiries to give the public confidence the facility will be independently regulated at all stages throughout its lifetime.

Processes for public participation must allow for all stakeholders to be free to comment on the Regulatory Body’s activities and be sufficiently robust to resist forces seeking to undermine proper policy processes. The licensing system must be efficient and not result in undue economic burdens on the licensee. In the case of nuclear power, investor concerns focus on administrative procedure costs, a fear of technical difficulties, and project delays incurred by long public inquiries. The Regulatory Body can address some of these concerns through the implementation of an efficient licensing process, having clear and transparent regulatory requirements and expectations, and having clear criteria against which safety cases will be assessed. The Regulatory Body should also work with the licensee to produce an agreed “Regulatory Schedule” for the construction, commissioning and initial operation of the nuclear facility. The Regulatory Schedule should align the project program with required “hold points.” It should also set out the dates for submission of the licensee’s nuclear safety and security documentation required for each “hold point.” Sufficient time should be allowed to enable the Regulatory Body to assess the documentation and give the necessary permission to proceed past the “hold point.”

The INSAG (2017) also recommends that Government and the Regulatory Body consult with independent advisory bodies; for example, the Advisory Committee on Reactor Safeguards supports the U.S. Nuclear Regulatory Commission (see Bley and Malsch, 2021a).

The adoption of the Convention on Nuclear Safety in 1994 legally binds participating countries to prepare and submit National Reports on the safety of their nuclear programs. The Regulatory Body usually contributes to the production of these reports and often leads on the presentation of the National Report at IAEA “peer review” meetings of the contracting parties.

Application of Defense-in-Depth

To ensure that the likelihood of an accident having harmful consequences is acceptably low and to mitigate any releases from such accidents, the Regulatory Body applies the Defense-in-Depth principle (INSAG, 1996). This principle requires the failure of several consecutive and independent levels of protection (barriers) before any harmful effects to people or the environment occur. Levels of protection include a combination of factors, such as remote site selection, engineering safety features, safety margin in design, diverse and redundant protection systems, operating procedures and practices, management commitment to safety and security, and a robust nuclear safety and security culture. When properly implemented, Defense-in-Depth ensures that the combination of failures that could give rise to significant harmful effects has a sufficiently low probability of occurrence. The Regulatory Body will also normally require that no single technical, human, or organizational failure should lead to undesirable consequences such as an uncontrolled release of radioactivity (often referred to as the single failure criterion).

The Regulatory Body may require the Licensee to apply the Defense-in-Depth principle in the assessment of external hazards and severe accidents. Table 1 lists the objectives and typical implementation methods for a Defense-in-Depth concept with five levels of safety. (INSAG, 1996) Methods identified in Table 1 consider design, construction, and operation activities as well as accident management procedures to mitigate unexpected events and arrangements for preparedness and response for a nuclear or radiation emergency. As noted above in the discussion of the “Triple Lock” and the “ISiD” philosophy, the Regulatory Body ensures wider application of the Defense-in-Depth principle by setting safety objectives, by conducting technical assessments of the safety justifications provided by the Licensee, and by performing inspections to check compliance with regulatory requirements.

Risk justification and assessment

International expectations require all new practices involving the use of radioactive materials be “Justified.” For facilities and activities to be justified, their benefits should outweigh potential radiation risks. It is not the role of the Regulatory Body to assess the benefits of a facility or practice; and hence, it is normally the Government that makes “Justification” decisions. The Regulatory Body may provide input to this decision by performing an independent review of the risks.

Table 1 Levels of Defense-in-Depth.

Level	Objective	Essential means
1	Prevention of abnormal operation and/or failures	Conservative design High quality in construction and operation
2	Control of abnormal operation and detection of failures (protection)	Control systems Limiting systems Protection systems
3	Accident control within design basis (protection)	Engineered safety features Accident procedures
4	Control of severe plant conditions (protection)	Complementary measures Accident management
5	Mitigation of radiological consequences of significant radioactive releases	Off-site emergency response

Courtesy of International Nuclear Safety Advisory Group (1996) *Defence in Depth*. INSAG-10, IAEA Publication 1013, Vienna.

The design of a nuclear facility or activity is considered to be optimized if it can be demonstrated the highest level of safety that can reasonably be achieved throughout its lifetime is obtained without unduly limiting its utilization. This approach requires the risk to either workers or the public arising from the exposure to ionizing radiation be reduced to ALARA or ALARP. The ALARA and ALARP concepts are not the same but are usually considered to have equivalence. The evaluation of both ALARA and ALARP requires some understanding of costs required to reduce the risk and the benefits of that reduction. The latter requires a value being placed upon a life. The Licensee is required to demonstrate that the design/modification/operating procedure/activity meets the ALARP/ALARA requirement, and the Regulatory Body is expected to assess the Licensee's case.

All radiation risks from normal operation, abnormal or accident conditions must be assessed (using a graded approach) prior to granting a license and periodically reassessed throughout the lifetime of the facilities and activities.

Radiation protection

Measures to control radiation risk aim to ensure that no individual bears an unacceptable risk of harm. The Licensee is required to apply ALARA/ALARP to all activities involving exposure to ionizing radiation. However, the Regulatory Body may impose annual limits to exposure. The Regulatory Body's inspection program should check exposure records on a regular basis. Also, the Licensee should be required to report any incidents resulting in an exposure that exceeds the limits.

Radiation risks may transcend national borders and persist for long time periods. In judging the adequacy of measures to control radiation risk, possible current and future consequences should be considered. The effects of radiation on the environment have been less thoroughly investigated and regulated. The general intent of measures taken for environmental protection have been to protect ecosystems against radiation exposure that would have adverse consequences for populations of species. Regulation can affect management of radioactive waste, which has the potential to place an undue burden on future generations, ensuring that safe, practicable, and environmentally acceptable solutions are employed for long term management.

Integration of nuclear safety and nuclear security

Safety measures and security measures have the common aim of protecting human life and health and the environment (WINS, 2011). As observed in (IAEA, 2006, 2010b), some safety principles concern the security of facilities and activities to the extent that they apply to measures contributing to both safety and security. Examples include the following:

- appropriate security provisions in the design and construction of nuclear facilities and installations, which can also support safety;
- controls on access to nuclear facilities and installations for safety purposes, which can also be used to prevent the loss of, and the unauthorized removal, possession, transfer and use of, radioactive material;
- arrangements to mitigate the consequences of accidents and failures, which can also be appropriate for dealing with breaches in security that give rise to radiation risks;
- security measures for managing radioactive sources and radioactive material, which can also support safety.

Safety measures and security measures must be designed and implemented in an integrated manner so that security measures do not compromise safety and safety measures do not compromise security (Williams, 2013b).

Regulatory attributes

Independence

The Regulatory Body must be independent of the nuclear industry and independent of those with policy responsibility for the promotion of the nuclear industry. Whilst the Regulatory Body cannot be entirely separate from other governmental bodies, the

Government must ensure the Regulatory Body is able to make regulatory decisions “without undue pressure or constraint.” To enable the Regulatory Body to exercise this independence, it must be technically competent and have adequate financial resources to ensure the recruitment and retention of high quality staff (INSAG, 2017; IAEA, 2016; OECD, 2014, 2016).

As discussed in Williams (2021), some Regulatory Bodies report to their Governments and some report to their national or regional parliaments. INSAG (2017) recommends Governments ensure independence by delegating to the Regulatory Body the formal authority to license nuclear installations. Some populations might prefer Government organizations to take the final and formal licensing decisions because elected and publicly accountable persons are responsible for final licensing decisions. However, this would run counter to INSAG recommendations because it could undermine the effective independence of the Regulatory Body. In addition, INSAG (2017) contends it is prudent for a specialized expert agency to issue licenses because of the complex political, sociological, and technical issues associated with nuclear power.

In order to maintain its independence, a Regulatory Body must avoid regulatory capture, such that it is not dominated by the commercial or political concerns of the industry or sector it is charged with regulating. Difficulties encountered by the U.S. Atomic Energy Commission, which had the responsibility for both promoting and regulating the nuclear industry, led to a 1957 decision that required public hearings on all licensing cases and that made the existing Advisory Committee on Reactor Safeguards a statutory body with the responsibility to independently produce publicly-available reports on licensing cases, and ultimately, a 1974 decision to establish a separate regulatory agency, the U.S. Nuclear Regulatory Commission (Walker and Wellock, 2010; Bley and Malsch, 2021a).

While the Regulatory Body must be independent from the nuclear industry, this does not mean it should operate in isolation. As emphasized in OECD (2014), the Regulatory Body needs to have frequent and open discussions with all its stakeholders. Although financial independence is a necessary attribute, the Regulatory Body is accountable to the national Government or other political authorities that authorize its funding. Systems for financial accountability vary and continue to evolve as discussed in Williams (2021).

Independence will only be achieved when the Government is prepared to accept regulatory decisions without interference. Government should not use the Regulatory Body as a vehicle to deliver its nuclear policy, nor should it try to control the Regulatory Body or align it with Government policy objectives.

Effectiveness

Key attributes of an effective regulator are provided in OECD (2014) and INSAG (2017). For example, INSAG (2017) displays the ISiD regulatory sub-system attributes as a series of layers, including internal capability, technical knowledge, organizational structure, processes, and external peer review (see Fig. 2).

The Regulatory Body must demonstrate its ability to establish and apply coherent requirements for nuclear safety and nuclear security, including those for human performance and quality. As the Regulatory Body has the prime responsibility for oversight of the licensee, it must have the authority, technical knowledge, capacity and capability to ensure the licensee has necessary technical competence, nuclear safety and security management structure, a robust nuclear safety and security culture and the necessary financial resources to deliver its responsibilities.

Leadership

Effective leadership is a vital attribute of any organization, and experience has shown that inadequate leadership has been a contributing factor in many accidents and failing organizations. The Regulatory Body is a key component in the delivery of safe nuclear power. Hence, strong and competent leadership is a prerequisite for a successful Regulatory Body. The public (who put their trust in the Regulatory Body for their protection), the nuclear industry (which needs a clear understanding of who is ultimately responsible for regulatory decisions), and the Government (which needs to know where regulatory accountability lies) need to know who is responsible for decision-making. There is a need for the senior nuclear regulator or regulatory panel, which has the ultimate power to take regulatory decisions, to be clearly identified.

Culture

The Regulatory Body must have a culture that promotes openness, transparency and accountability. Several references (INSAG, 2017; IAEA, 2016; OECD, 2014, 2016) indicate that the promotion of “safety culture” is reinforced by conducting safety performance assessments or inspections and the use of a structured lessons learned process.

Regulatory approaches

The Regulatory Body may consider the use of various regulatory approaches. These include prescriptive based, goal-setting based, risk- and hazard-informed based, process based, self-assessment based, and education/influence based (OECD, 2014). Summary information for the first three types of approaches are provide here to illustrate their benefits and disadvantages. More detailed descriptions may be found in OECD (2014).

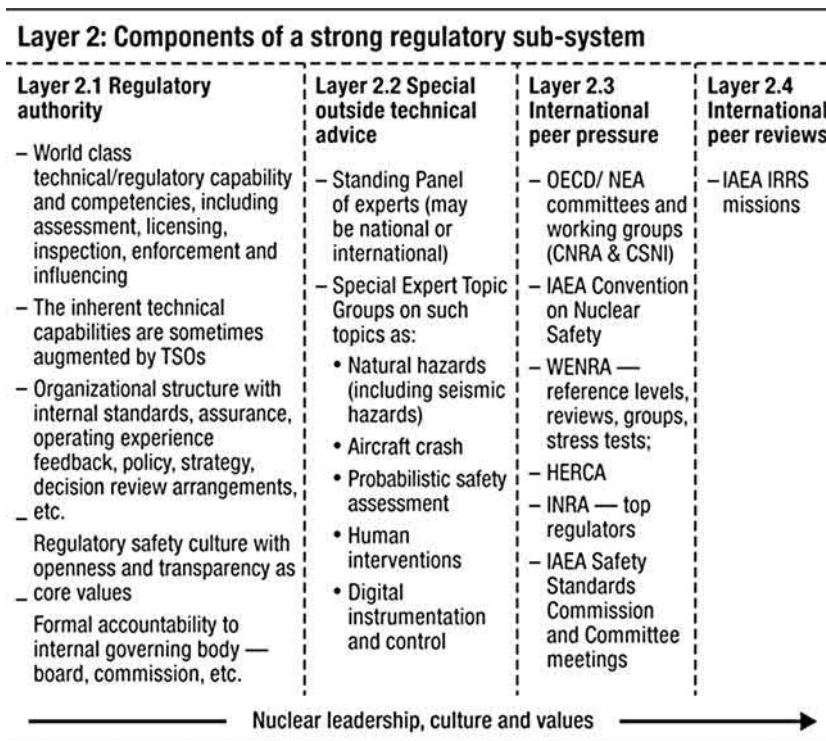

Fig. 2 Examples of the components of a strong regulatory sub-system [CNRA, Committee on Nuclear Regulatory Activities; CSNI, Committee on the Safety of Nuclear Installations; HERCA, Heads of European Radiological Protection Competent Authorities; IAEA, International Atomic Energy Agency; IRRS, Integrated Regulatory Review Service; INRA, International Nuclear Regulators Association; OECD/NEA, Organization of Economic Cooperation and Development Nuclear Energy Agency; TSO, Technical Support Organization; WENRA, Western European Nuclear Regulators Association]. International Nuclear Safety Advisory Group (2017) *Ensuring Robust National Nuclear Safety Systems—Institutional Strength in Depth*. INSAG-27, IAEA Publication 1779, Vienna.

Prescriptive approach

In this approach, the requirements on methodologies, standards, and quality assurance are prescribed by the Regulatory Body. The licensee must demonstrate the plant complies with these regulatory requirements. In addition, regulatory guidelines, describing methods acceptable to the Regulatory Body, may be provided. As discussed in [Bley and Malsch \(2021a,b\)](#), the U.S. Nuclear Regulatory Commission regulations were initially developed as a prescriptive approach.

A major benefit of a prescriptive approach is the level of clarity for both the regulator and the licensees. An additional benefit in some situations is that the approach can be used to exert specific regulatory authority. This approach, however, has several difficulties. The main difficulty is that by defining specific requirements against which the Licensee must comply, it can be argued that the Regulatory Body is assuming responsibility for plant safety. The prescriptive approach also requires the Regulatory Body to have sufficient technical competence to match the regulations with the nuclear safety, security and environmental protection requirements. It also places a great responsibility on the Regulatory Body to get it right as the industry will in general aim to comply with the required regulations. The approach can also be resource-intensive for regulators and inflexible for licensees and operators.

Goal-setting approach

This approach is used by the Regulatory Body to establish specific performance goals or outcomes for licensees to attain but does not specify how they must be attained. Licensees determine how they will conduct their work activities. The United Kingdom licensing system provides an example of a non-prescriptive approach. As discussed in [Williams \(2021\)](#), the Office for Nuclear Regulation (ONR) sets goals, but the Licensee can undertake whatever action it chooses to meet these targets. This approach puts the responsibility for nuclear safety, security and the protection of the environment clearly on the Licensee. The Licensee is required to demonstrate that its facility is safe, nuclear materials are secure, and the environment is protected. The Regulatory Body will assess the adequacy of the Licensee's safety case against its own safety, security, and environmental principles to ensure that the goals have been met.

A major benefit of a goal-based approach is that it allows licensees to select optimal methods to meet safety goals. This approach is more flexible for new technologies and encourages licensees to improve plant performance. However, a goal-based approach

presents some difficulties for the Regulatory Body in identifying good performance goals and quantifying outcomes. It can also present difficulties for the Licensee in that regulatory expectations are less clear than found in a prescriptive approach.

This approach requires a technically competent Licensee. It also requires a technically competent Regulatory Body to be capable of independently assessing the arguments made and the information presented before permissioning specific Licensee activities.

Risk-informed and hazard-informed approaches

Risk-informed and hazard-informed approaches are used by the Regulatory Body to determine the risk or hazard associated with an issue to determine the appropriate level of regulatory attention. A risk-informed approach considers the probability and potential for harm to identify areas of greatest risk. A hazard-informed approach uses specific criteria to identify areas of greatest potential for harm. As discussed in [Bley and Malsch \(2021b\)](#), the U.S. Nuclear Regulatory Commission is moving toward a more risk-informed regulatory approach.

Risk- and hazard-informed approaches are beneficial because regulatory attention is focused on prioritized safety issues. However, Regulatory Bodies using these approaches must consider risk and hazard assessment limitations, such as the lack of completeness, which could result in some areas receiving inadequate or too much attention.

Future considerations

Regulation continues to evolve. Several factors that may impact current regulation are harmonization of regulatory requirements, advanced reactor regulation, and interfaces between nuclear safety, nuclear security, and non-proliferation safeguards.

Harmonization of regulation

Despite similarities in the objectives, attributes and functions, there are differences in regulatory requirements across the world. As noted in the [Introduction](#), the main reasons for this revolve around the fact that regulation is law enforcement and there is no universal legal system covering all countries that are using nuclear energy. Differences also relate to: national energy policy; national industrial tradition (e.g., giving more credit to redundancy or diversity, or crediting a software-based system as opposed to hard-wired controls); consistency with national regulatory or legislative system (e.g., compliance with probabilistic safety criteria on individual and societal risk as applicable to the environmental policy); country-specific conditions (e.g., differences in geography such as potential flooding and seismic hazards); and consideration of uncertainties associated with severe-accident phenomena.

The Nuclear Safety Convention and the supporting IAEA safety standards may be used by Regulatory Bodies to benchmark their approaches and promote a measure of equivalence to be achieved. Efforts by Regulatory Bodies to work together through organizations, such as the International Nuclear Regulators Association (INRA), the Western European Nuclear Regulators Association (WENRA) and the OECD/NEA, have led to some harmonization of safety requirements and regulatory practices.

Regulation for advanced reactors

The regulatory framework and the Regulatory body should be capable of regulating any nuclear technology. As discussed in [Bley and Malsch \(2021a\)](#), [Rempe \(2021\)](#), and [Williams \(2021\)](#), some regulatory frameworks have been effectively regulating non-LWRs for many years. Most nuclear reactor regulatory requirements are, however, focused on large LWR designs. Attempts to license other designs (e.g., Small Modular Reactors and non-LWRs) are often hindered by existing regulatory requirements. Some existing regulatory requirements aren't applicable to specific advanced designs. [Bley and Malsch \(2021b\)](#) describes on-going activities by the U.S. Nuclear Regulatory Commission to develop new "technology inclusive" regulatory approaches better suited for such designs. Of particular interest are the so-called advanced reactor technologies with enhanced margins for safety such that a regulator could approve smaller emergency planning zone sizes, different engineered safety feature requirements (including the elimination of large leak-tight containment buildings and different approaches for calculating source terms) and exemptions from technology-specific design criteria. As discussed in [Bley and Malsch \(2021b\)](#), the use of risk-informed, performance-based approaches is emphasized to develop a more flexible licensing approach applicable to diverse technologies.

Interfaces between safety, security and non-proliferation requirements

To ensure that the public is adequately protected, it is now recognized that Regulatory Bodies must also address nuclear security and non-proliferation safeguards. Such issues increased in importance in the 1970s because of growing concerns about terrorist groups ([Walker and Wellock, 2010](#)). This led Regulatory Bodies to strengthen regulatory requirements for the transportation of nuclear materials and for nuclear plant security. Some Regulatory Bodies also implemented measures that would limit the export of nuclear materials and technologies associated with the proliferation of nuclear weapons. Following the terrorist attacks in the U.S. on September 11, 2001, increased security measures and practices at nuclear facilities were implemented. The result was significant enhancements to the design and operation of nuclear plants that strengthened Defense-in-Depth against malevolent behavior. Additional effort is needed to integrate regulatory requirements for safety, security, and non-proliferation safeguards.

Glossary

Atomic Safety and Licensing Board (ASLB) Three-member atomic safety and licensing boards conduct public hearings on license applications and challenges to licenses for the U.S. Nuclear Regulatory Commission (NRC).

Backfitting A backfit occurs when the NRC changes its mind about the safety of a licensed facility and wants a plant to add additional protection; i.e., make modifications to installed equipment.

Code of Federal Regulations (CFR) Regulations promulgated by U.S. government agencies. Commercial nuclear energy facilities are governed by 10 CFR Parts 1–199 promulgated by the NRC.

Engineered Safety Features Plant systems designed to reduce the likelihood or consequences of possible accidents.

FLEX An industry-developed set of standard flexible adaptations to plant equipment and operating procedures to allow plant operators to quickly attach portable mechanical or electrical components in case of failure of installed equipment—known as “Diverse and Flexible Coping Strategies.”

General Design Criteria A set of broad plant design criteria defined in Appendix A to 10 CFR Part 50. The intent was to define criteria such that, if applicants could demonstrate that their design would meet them, it could expedite the licensing process and make it more predictable.

Joint Committee on Atomic Energy Joint committee of the U.S. Senate and House of Representatives that oversaw the nuclear stockpile and technology following World War II and promotion and regulation of commercial applications of nuclear energy until 1977.

kw kilowatts.

Manhattan Project The World War II government agency that developed nuclear weapons.

mw megawatts.

Probabilistic Risk Analysis An approach to safety analysis that identifies what can go wrong and quantifies the likelihood and consequences of each scenario. Risk of a facility is presented in terms of the probability of various consequences, including rankings of contributors to the risk and a formal treatment of uncertainty.

Safeguards Committee In this chapter, this refers to the original Reactor Safeguards Committee and its successor, the Advisory Committee on Reactor Safeguards. It is an advisory committee established by statute to advise the NRC (formerly the Atomic Energy Commission) on matters of nuclear safety.

Regulatory Guides Guidance documents from the NRC that provide applicants with acceptable ways to meet the regulations.

Safety Analysis Report A formal document that must be submitted by applicants to obtain licenses for commercial nuclear plants.

Source Term the radionuclide content, release locations, and energy content of possible releases following accidents.

Standard Review Plan The guidance for NRC staff on how to review applications.

Technical Specifications A set of plant specifications that define what technical information is vital for evaluating nuclear safety and provide an acceptable range of operating limits.

U.S. Nuclear Regulatory Commission (NRC) The body established by the Atomic Energy Act, as amended, to regulate civilian applications of nuclear power in the United States (formerly the Atomic Energy Commission).

Introduction—Institutional evolution and technical issues

Nuclear energy was introduced to the world through weapons developed by the Manhattan Project during World War II. The first nuclear device, 'Trinity,' was detonated at Alamogordo, New Mexico on July 16, 1945. Less than 1 month later, the bomb, 'Little Boy' was dropped on Hiroshima and 3 days later 'Fat Man' was dropped on Nagasaki. This beginning, as the most terrifying weapon in history, strongly influenced the administration and application of nuclear science in the early years and has colored popular concerns ever since.

The institutional milieu

Following the war, the reactors, laboratories, and material of the Manhattan Project were transferred to a new agency, the U.S. Atomic Energy Commission (AEC) with the passage of the Atomic Energy Act of 1946. It focused on the military applications of nuclear energy and the associated need for secrecy. While the act acknowledged a growing recognition of possible peaceful uses of atomic energy, applications of the technology were restricted to U.S. Government activities. The act also created the Joint Committee on Atomic Energy (the "Joint Committee"), a unique and powerful oversight body with members from both the Senate and the House of Representatives, and the unique authority to report proposed legislation simultaneously to both houses of Congress. Developments were moving quickly. 1954 marked the U.S. Navy launch of the first nuclear powered submarine, U.S.S. Nautilus. Political pressure for developing civilian applications grew, both for envisioned technical benefits and to retain the U.S. position as the leader in the field. In 1953, President Dwight D. Eisenhower offered that "this greatest of all destructive forces can be developed into a great boon, for the benefit of all mankind" (Walker and Wellock, 2010).

A new law, the Atomic Energy Act of 1954, opened the possibility of peaceful, civilian use of nuclear energy. It also marked the beginning of nuclear regulation in the U.S., by directing the AEC to prepare regulations to protect the public. The AEC would now have three functions: manage the weapons program, promote civilian commercial uses of nuclear power, and protect the public health and safety from associated radiation hazards. Jumping ahead several decades, the conflict among these competing responsibilities, eventually damaged AEC's credibility on regulatory and safety issues. The Energy Reorganization Act of 1974 separated those responsibilities, with the military and promotional activities assigned to a new agency, the U.S. Energy Research and Development Administration (which later became the U.S. Department of Energy) and the safety regulatory activities assigned to a new agency, the Nuclear Regulatory Commission (NRC).

Returning to the first years of the AEC, the Commissioners formed the Reactor Safeguards Committee, out of concern for reactor safety issues. The Committee's first task in 1947 was to survey the nuclear reactors already operating to evaluate problems peculiar to design and siting. In 1950, the AEC formed another advisory committee, the Industrial Committee on Reactor Location Problems, with representatives from the electric-power industry and industrial-research corporations. They were tasked to examine the hazards associated with AEC production facilities, especially reactor-siting questions, and to consider classified agency activities for possible commercial development. The two committees were combined in 1953 as the Advisory Committee on Reactor Safeguards (ACRS).

Commercial nuclear power was a new field and the Atomic Energy Act of 1954 gave the AEC broad authority on how the promotional and regulatory aspects should be managed. While the AEC and the Joint Committee agreed on the high-level policy issues, the details were often contentious. Within a few years, Congress passed a 1957 amendment to the Atomic Energy Act of 1954. Among other things, this act established the ACRS as a statutory committee and required that ACRS review every construction permit or operating license application for a new commercial or test reactor and publish a public report on their review. This role continues to the present day.

In 1954, the AEC was facing the beginning of a new commercial industry and with respect to licensing, they were starting with a nearly blank slate. There was guidance from the National Committee on Radiation Protection (NCRP) on radiation protection guidelines. However, no other aspects of possible regulatory concern were in place. In 1955 the AEC created the Division of Licensing and designated a Reactor Hazards Evaluation Staff. During the same time period, the Joint Committee was looking for ways to allow greater public confidence in the AEC's regulatory process. The 1954 Atomic Energy Act had required public hearings on reactor construction permit and operating license applications only if potentially affected persons requested them. In order to promote public confidence in the licensing process, the 1957 amendment to the Atomic Energy Act required the AEC to hold mandatory public hearings on license applications for commercial and test reactors. These requirements proved more difficult than expected, when opposition to nuclear power projects increased. During the period 1957–62 extensive interactions among the Joint Committee, the AEC, and expert groups from government, industry, and academia led to several attempts to implement the hearing requirements. The AEC established a formal legal separation of the licensing staff from the hearing staff. In 1958, they set

up an Office of Hearing Examiners, which later, in 1962, became the source of the Atomic Safety and Licensing Board (ASLB) members. In 1959, based on the recommendation of the AEC, another amendment to the Atomic Energy Act allowed the AEC to enter into agreements with states, giving them certain regulatory responsibilities. In 1962 the Atomic Energy Act was amended to allow three-member ASLBs to conduct hearings and, in 1969, the AEC established an ASLB Appeal Panel. The 1974 amendment to the Atomic Energy Act finally directed separation of the weapons and promotional activities of the AEC from their regulatory responsibilities. The new NRC was established in 1975.

In parallel with this rapid organizational evolution, commercial nuclear power plant designs and applications for licenses proceeded at a rapid pace. In 1953, the Shippingport pressurized light water breeder reactor project was initialized as a combined effort among the AEC, Naval Reactors, Westinghouse, and Duquesne Light Company. In 1955, the AEC announced the Power Demonstration Reactor Program (Wiley, 1955) (later called the Cooperative Power Reactor Demonstration Program [AEC, 1963]). It was a government/industry cooperative effort to develop, construct, and operate experimental power reactors. Some new reactors were proposed to be developed using private funds alone. During 1955, applications were received for a number of reactors: Dresden, a BWR by Commonwealth Edison Company and General Electric Company; Vallecitos, a BWR experimental reactor by General Electric Company; Yankee Rowe, a PWR by Yankee Atomic Electric Company and Westinghouse; Hallam, a sodium graphite reactor by Consumers Public Power District of Nebraska; Fermi, a fast breeder reactor by Power Reactor Development Company; Elk River, a closed cycle BWR by Allis Chalmers; Piqua, an organic-cooled and moderated reactor by Atomics International. In 1956, the AEC issued construction permits for Indian Point, a PWR by Consolidated Edison, and Dresden, a BWR by Commonwealth Edison. There were even more in the following year. See Remppe (2021b) for a more complete discussion of the government/industry cooperative programs.

Regulatory process

As the AEC embarked on developing a system of regulation, a 1955 statement by the acting Chairman of the Commission provided a safety philosophy that was marvelously prescient (Libby, 1956): “the ultimate safety of the public is dependent upon three factors:

1. Recognizing all possible accidents which could release unsafe amounts of radioactive materials;
2. Designing and operating the reactor in such a way that the probability of such accident is reduced to an acceptable minimum;
3. By appropriate combination of containment and isolation, protecting the public from the consequences of such an accident, should it occur.”

The evolving regulatory process can be seen as a series of attempts to meet these goals, first by creatively applying engineering judgment, then by attempts to bound each criterion, and eventually finding a way to quantify each of them. The last approach has become known as probabilistic risk assessment (PRA) and it provides quantification of the ‘risk triplet’ (Kaplan and Garrick, 1981):

1. What can go wrong?
2. How likely is it that it will happen?
3. If it does happen, what are the consequences?

which is remarkable similar to the three factors described by Libby.

The evolution of regulatory practice at NRC has much to do with developing and refining approximations to Libby’s three criteria, even when many of those involved would not have expressed it that way. There were no regulations in the late 1940s and early 1950s, and the AEC had a very small staff. During that time, the AEC relied heavily on the expertise of the Reactor Safeguards Committee (later the ACRS). The physicist, Edward Teller, who chaired the Safeguards Committee for 6 years, pointed out that the historic industrial practice of trial and error was not sufficient for nuclear reactors, because of the nature and extent of possible consequences of an accident. He described a ‘simple procedure’ the Committee had developed to structure its reviews of safety (Teller and Brown, 1962): for each reactor, they asked the designers to “imagine the worst possible accident and to design safety apparatus guaranteeing that it could not happen... The committee reviewed each reactor plan, trying to imagine an accident even worse than that conceived by the planner. If we could think of a plausible mishap worse than any discussed by the planner, his analysis of the potential dangers was considered inadequate. In most cases, the required discussion created a reasonable spirit of caution, and we could advise the Atomic Energy Commission that the reactor would be sufficiently safe” (Mazuzan and Walker, 1984). The Safeguards Committee was exercising their judgment to approximate Libby’s first and third principles.

The AEC institutionalized and systematized this ‘simple procedure’ in the early 1950s by requiring a hazards-summary report (later renamed the safety analysis report) on each planned facility. “The report had to include a description of the reactor and the site, a detailed plan of operation, a schedule of chemical processing and disposal of reactor fission products, the methods of disposal of radioactive effluents, and a description of the safety mechanisms of the reactor. More specific information was required on potential hazards, incorporating the data used in the safety-evaluation procedure described by Teller. The designer had to list all the known potentially hazardous features and include the experimental information, calculations, and assumptions used in evaluating those hazards. The report required information on steps taken to minimize the risks and an estimate, if a failure should occur, on the extent of any release of radioactive material and the damage to be expected... Regarding the site of a reactor, the report required consideration of hydrological data including the expected drainage of liquids in case of a major accident, seismic data including estimates of potential damage that might occur in the event of earthquakes of various intensities, and atmospheric conditions including an assessment of dangers to the surrounding population and industries. In addition, contractors had to provide

information on the distribution of population and list vital industrial, defense, and public-service installations within the possible hazard radius of the facility... This extensive report became a standard document by which the AEC staff and the Safeguard Committee judged the hazards of a reactor" (Mazuzan and Walker, 1984; AEC, 1951). These reports were based on data and analysis to the extent possible; they also relied heavily on engineering judgment, by applicants, AEC staff, and advisors.

The AEC and the Joint Committee negotiated specific kinds of facilities to be licensed: 'Class 103' licenses (named for Section 103 of the 1954 Atomic Energy Act) for commercially viable facilities and 'Class 104' licenses for test and research reactors, as well as demonstration power reactors (104b). Early power reactors received Class 104b licenses. By the 1960s commercial nuclear power was established and applications for large power reactors were coming to the AEC; however, Class 104b licensing continued. The AEC argued that it could not judge if reactors were commercially viable until long-term operating experience was available. Congress disagreed and in 1970 amended the Atomic Energy Act of 1954, removing the requirement from Section 102 that a reactor must be sufficiently developed to be of practical value, before issuing a Class 103 license. It required licenses issued to commercial facilities to be issued under Section 103, unless already licensed under 104b or developed under the Cooperative Power Reactor Demonstration Program (Walker, 1992).

The institutional milieu again

By 1954 the application review load was becoming more than the part-time Safeguards Committee could support. In 1955, the AEC established the Reactor Hazard Evaluation Staff, which was to take on more of the application review process, with oversight by the Safeguards Committee. Over the years, as AEC staff grew, the agency passed through several reorganizations. By this time, quantitative criteria for radiation exposure to workers and the general public had been established by the NCRP. During 1955 the AEC published their own proposed radiation protection standards and have revised them several times since, based on new information and recommendations by NCRP.

Through a series of efforts, the agency and the Safeguards Committee negotiated issues of reactor siting, hypothetical accident source terms (the radionuclide content, release locations, and energy content of possible releases), the probability of a major accident, and emergency planning. In parallel, there evolved a process of formalizing accident analyses, improving quantification, and addressing uncertainty. AEC and later NRC regulations for civilian facilities are tabulated in Title 10 CFR Parts 1-199 of the Code of Federal Regulations (GPO, 2019, 2020).

Siting and source terms

The first attempt to address siting issues was the Safeguards Committee's report (AEC, 1950) that recommended for AEC reactors that the general public be excluded from a circular area of *adius (in miles)* = $0.01 \sqrt{\text{power in kw}}$, based on calculations of maximum possible releases. As the AEC began to consider power reactors for electrical distribution, this simple isolation criterion became impractical (for a 100 kw research reactor the exclusion radius would be 0.1 miles, but for a 3000 mw power reactor, the radius would be over 17 miles). For economic electric power distribution, reactors would need to be much closer to population centers. Therefore, focus began to shift from isolation to engineered safeguards to prevent and mitigate possible accidents. For example, emergency core cooling systems were developed to reduce the likelihood of the release of fission products from the core and containments were designed to block any release from the plant, should the core be damaged. The first nuclear power plant containment was built at West Milton, NY, in the early 1950s and it set a precedent that has been followed by all light-water reactors (LWRs) in the U.S. All have included some type of containment system and physical structure, designed to withstand the most severe over-pressure events identified for the specific reactor design (Okrent, 1981; Kerr, 1989; ACRS, 2018).

Siting requirements and evaluation of potential source terms evolved from the bounding approach of WASH-3, to the siting criteria of 10 CFR 100, which established the following distance definitions for commercial reactors:

1. An 'exclusion area' completely controlled by the licensee, such that an individual located anywhere on its boundary for 2 hours following a release would not receive a dose to the whole body in excess of 25 rem or to the thyroid of 300 rem
2. A 'low population zone,' such that an individual located anywhere on its boundary for the entire period of the release would not receive a dose to the whole body in excess of 25 rem or to the thyroid of 300 rem
3. A 'population center distance' of at least $1 \frac{1}{3}$ times the distance from the reactor to the outer boundary of the low population zone.

Calculation of these siting distances was based on conservative (in the sense that calculated required distances are greater than if more accurate calculations could be made) assumptions and approximations of the physical and chemical phenomena that control the release and dispersion of fission products, as well as the dose received by individuals at various distances from the plant (DiNunno et al., 1962). The authors of this report, TID-14840, make the point that consideration of the consequences of an accident cannot be considered independent from the probability of the accident. Their recommendations are based on stylized scenarios for the types of accidents they considered. They are not offered as acceptable doses in general, but as reasonable reference values for well-designed plants with very low probability of a severe accident. Their results became known as the 'TID source term' and remain the acceptable basis for evaluating radiological consequences of reactors whose owners applied for licenses before January 1997 and choose to continue its use (US NRC, 2003a,b).

Plants that applied for licenses after January 1997 (and older plants that choose to change their licensing basis) use more recent “alternative source terms” (Soffer et al., 1995) based on new information and experiments providing a more thorough understanding of the timing, magnitude, and chemical form of fission product releases from reactor accidents. Use of the alternative source terms changes the dose criteria for the exclusion area and low population zone, from separate whole body and thyroid doses to 25 rem total effective dose equivalent (TEDE) (US NRC, 2000).

The institutional milieu again

Let us return to Libby’s three criteria. The AEC has by now addressed the issue of recognizing all possible accidents primarily by engineering judgment. As for designing and operating the reactor in such a way that the probability of an accident is reduced to an acceptable minimum, qualitative approximations for ensuring high reliability have been developed, such as the single failure criterion, which requires that any engineered safety system must be able to carry out its safety function despite of the failure of any single component within the system or within an associated support system (US NRC, 2003a, 1977b).

The industry has made great strides in designing emergency core cooling systems that can respond to the accidents judged most important, and containment systems to withstand anticipated overpressure events. Coming to grips quantitatively with the probability of a severe accident and understanding containment capability for a range of core damage accidents will take some years. Finally, a balance between isolation and engineered safety features has been addressed in an approximate, but conservative way.

Technical specifications, general design criteria, and backfits

The AEC (and later the NRC) published an extensive catalog of regulations. However, demonstrating that an application met these regulations became cumbersome. Even modest design changes led to new rounds of hearings. The AEC staff looked for ways to set clear criteria that applicants and licensees could apply unambiguously. The first approach, developed during the period 1962–68, was to publish a set of technical specifications. They were to define what technical information was vital for evaluating nuclear safety and provide an acceptable range of operating limits. If the plant remained within those limits, a licensee could modify the design or operation of the plant without AEC approval. Specific criteria were provided describing remedies should the plant not maintain operations within the technical specifications. Another problem had developed—applicants expressed uncertainty about the depth of technical information needed to support a construction permit—that led to delay following an Atomic Safety and Licensing Board hearing and review. It appeared that a set of design criteria could expedite the licensing process and make it more predictable (AEC, 1965). By 1965 the AEC staff proposed a set of design criteria to the Commission and the Safeguards Committee. Applicants would need to demonstrate that their design would meet these broad criteria. After several years of negotiation with ACRS and stakeholders from industry, AEC issued the ‘general design criteria’ (GDC) as Appendix A to 10 CFR Part 50 in 1971. The criteria told applicants what was needed, not how to accomplish it.

During this same time period, the issue of ‘backfitting’ became contentious. Essentially, a backfit occurs when the NRC changes its mind about the safety of a licensed facility and wants a plant to add additional protection; i.e., make modifications to installed equipment. This became troublesome when applicants and the AEC disagreed about newly raised issues after work under a construction permit was complete and the application for an operating license was being reviewed. Industry was concerned with the high costs of backfitting; ACRS was concerned that important safety issues might not be addressed if backfitting were proscribed; and the AEC, still having promotional responsibilities, was concerned with the economic attractiveness of nuclear generation compared to coal. The AEC staff had been addressing this issue on a case by case basis. In 1970, the Commission adopted an amendment to 10 CFR 50 that required backfitting only when it provided substantial, additional protection. The burden to show substantial safety improvement was on the AEC staff (AEC, 1969; Okrent, 1981). The new general design criteria, discussed in the previous paragraph, helped avoid the backfitting controversy: once an applicant showed that they would meet the GDC, the likelihood of the AEC requiring a backfit following construction turned out to be much lower.

For many years the rule (10 CFR Part 50.109) provided simply that backfitting may be required if the Commission finds that “such action will provide substantial, additional protection which is required for the public health and safety or the common defense and security.” On its face, this was a high standard, implied by the use of “substantial, additional protection” that is “required.” In practice, the rule was rarely invoked, and it failed to address some key issues, including whether economic costs to be incurred by the licensee (and electricity consumers) in accomplishing a backfit could be a relevant factor in deciding whether the backfit was “necessary.” In 1983 the NRC began a rulemaking to address these and other issues and, in 1988, issued a new backfit rule that remains essentially the same today. The 1988 rule embodies a two-step safety philosophy as follows. The Commission must assure an “adequate” level of protection regardless of economic costs, as required by Section 182 of the Atomic Energy Act and will order a backfit to a design (or a procedure) to accomplish this. However, once an adequate level of safety protection is achieved, the Commission may under Section 161i of the Atomic Energy Act consider and take economic costs into account in ordering further safety improvements (backfits). It was soon recognized that probabilistic risk assessments can play an important role both in defining what level of protection is “adequate,” and in deciding whether a proposed backfit adds “substantial additional protection.”

Another issue was a long-running problem for the AEC and NRC, the growing list of ‘unresolved safety issues’ and ‘generic safety issues’ that were identified during license application reviews for specific plants. Such issues were often put aside for generic resolution, because they applied to a class of plants, not just the current application. How this problem was eventually resolved is discussed in Bley and Malsch (2021).

Guidance for meeting the regulations

Starting in the early 1970s, the AEC published a variety of guidance documents supporting its regulations. The Standard Review Plan (SRP) (US NRC, 2007) provides guidance to the regulatory staff for reviewing applications. Also, an extensive set of Regulatory Guides provides applicants with approved methods and approaches for meeting the regulations. Two of the Regulatory Guides (US NRC, 2018b, 1978) provide guidance for the content of applications and safety analysis reports respectively.

The earliest of these Regulatory Guides provided acceptable methods for addressing many of the issues that had concerned the ACRS and the regulatory staff, including some that led to the GDC; e.g., net positive suction head for engineered safeguards pumps, thermal shock to reactor pressure vessels, evaluating radiological consequences following accidents, control of combustible gas concentrations, independence between electric power sources, periodic testing, quality assurance, seismic design, and the single failure criterion.

The identification and review of potential operational events—transients and accidents—became more systematic as well. The SRP Chapter 15 (US NRC, 2007) now categorizes events by both their frequency of occurrence and by ‘type’ based on their effect on the plant. The frequency categorization includes:

- Anticipated Operational Occurrences (AOO), which are events expected to occur one or more times in the lifetime of the plant.
- Accidents, which are postulated, but not expected to occur in the lifetime of the plant.

The AEC/NRC has different criteria for evaluating AOOs and accidents. Other earlier guidance (US NRC, 2018b, 1978) separates AOOs into events of moderate frequency (i.e., they are expected to occur several times over the plant lifetime—also called Condition II events in ANS standards) and infrequent events (i.e., they may occur in the plant lifetime—Condition III events). Postulated accidents are called Condition IV events.

Design-specific specializations of AOOs are addressed in separate sections of the SRP. Very rare accidents with frequencies less than approximately 1×10^{-5} per year are called beyond-design-basis events and are not analyzed in the safety analysis report (US NRC, 2007; Apostolakis et al., 2012).

Operational events are categorized by the following seven types, based on departures from steady-state operation:

- Increase in heat removal by the secondary system (e.g., steam line break)
- Decrease in heat removal by the secondary system (e.g., turbine trip)
- Decrease in reactor coolant system flow rate (e.g., reactor coolant pump trip)
- Reactivity and power distribution anomalies (e.g., control rod drop)
- Increase in reactor coolant inventory (e.g., inadvertent safety injection)
- Decrease in reactor coolant inventory (e.g., loss of coolant accident)
- Radioactive release from a system or component (e.g., unisolated steam generator tube rupture)

This type of categorization can assist the applicant in conducting a thorough search for possible AOOs and accidents. Within each type, the applicant must identify events that challenge diverse operating limits; e.g., challenges to over-pressure or thermal margin.

The likelihood of an accident

The importance of the probability of an accident was discussed during the development of source terms and is more directly considered in the treatment of operational events. Some of the concepts here have evolved with expanded use of PRA. The idea of risk is imbedded in the GDC. They are structured to prevent relatively frequent events from generating serious consequences, while unlikely events are allowed to incur more severe consequences. Specifically, AOOs should not challenge the integrity of the reactor coolant system, main steam piping, or fuel cladding. A postulated accident should not result in off-site doses in excess of the guidelines of 10 CFR Part 100, but there could be substantial damage to the plant. There are also a number of analysis assumptions that must be used in the safety analysis, as well as requirements on calculated results.

The design basis accidents to be analyzed in the reactor safety analysis were not intended to be specific event sequences as would be analyzed in a PRA. They were intended to be stylized composites or surrogates to allow deterministic bounding (i.e., conservative) evaluation of the reactor’s engineered safety features—will they fulfill their functions under a variety of challenges, with margin. These analyses should ensure that the level of defense-in-depth can compensate for uncertainties in accident progression and analysis data (US NRC, 2000, 2003b; Drouin et al., 2016). The analyses are characterized by the use of prescribed and conservative methods and data, and, for each credited protection or safety system, by the assumption of the most limiting single active failure.

This approach has served the regulator and the U.S. industry well. However, it fails to address the question of the probability of a serious accident. In 1965, Glenn Seaborg, Chairman of the AEC, sent a letter to the Joint Committee stressing the low probability of a catastrophic accident, but acknowledging that the consequences could be severe (Seaborg, 1965). Unfortunately, at the time, we still had no convincing way to calculate the probability of a severe accident and our consequence calculations compounded many strongly conservative and sometimes conflicting assumptions. Following 1965, there were many unsuccessful attempts to solve the problem. Among the most important issues were the difficulty of imagining all the possible paths to failure and the need for practical mathematical methods to calculate the reliability of complex systems. In 1972, the AEC commissioned the Reactor Safety Study (Rasmussen and Levine, 1975) to quantify the probability of a severe reactor accident. The study was led by Prof. Norman Rasmussen of MIT and Saul Levine of the AEC staff.

Rasmussen and Levine turned to the aerospace and chemical processing industries for expertise on new methods of reliability analyses (Vessely et al., 1981). One of their intermediate products was a gigantic fault tree with core damage as the 'Top Event'. This tree modeled all the combinations of failures that could lead to the Top Event. It was so big that it covered the ceiling and walls of a large conference room. This made technical review of the work nearly impossible and use of the structure of the model difficult, at best. The team searched for a way to add simplifying structure. Rasmussen and Levine visited the Sloan School at MIT and talked with decision analysts; the decision trees used in that work sparked a breakthrough (Bley, 1975). Rasmussen and Levine imagined a similar tree structure, one they called an event tree on critical safety functions. Each event tree would begin with an 'initiating event' followed by a series of questions about the success or failure of the safety functions that could prevent fuel damage or mitigate it. Paths through these trees became known as event sequences or scenarios and represented, usually in proper time order, how the plant sequentially responds to the initiating event. This restructuring provided significant advantages:

- The overall PRA model could be more easily reviewed, and its results interpreted
 - It is now organized into digestible pieces
 - Initiating events are separated from the response of engineered systems to those events
 - Interactions among plant systems are clearly displayed
- The analysis was organized similar to how the plant responds, which
 - Allows specialization of thermal-hydraulic and neutronic response to each specific pathway (or scenario) through the analysis; importantly, when one tries to layout all possible scenarios, each leading to different levels of challenge, many more engineering calculations are required than for more simple bounding approximations.
 - Makes clear the path dependence of safety system, physical barrier, and human performance
 - Provides better understanding of the importance of systems, components, and operators
 - Allows coupling of similar plant scenarios with phenomena that can lead to core damage and fission product release

The Reactor Safety Study was a massive undertaking involving something like 70 staff years by AEC staff and contractors, as well as a like amount donated by vendors, licensees, and interested parties (Bley, 1975). Much of this effort occurred because it was a first of a kind study that involved the development of new methods, many trial approaches, and substantial manual effort. In the years that followed the Reactor Safety Study methods were extended and refined, and computer codes were developed to automate much of the manual effort. In addition to providing the first convincing estimate of the risk from commercial nuclear power plants, important insights included the fact that the risk was higher than previously believed, several non-safety grade systems useful when secondary heat removal is lost were shown to be important to risk, loss of electric power was especially important because it affected nearly all plant systems, a number of failure sets previously described as common-cause failures were identified as support system to front line system dependencies that could be modeled explicitly. The study marked the first time the chain of events following core damage were explicitly modeled to estimate the likelihood of various kinds of release from the containment. Thus, given a core melt, some pathways lead to containment failure and release, some bypass the containment leading to release, and some lead to an intact containment and no substantial release. For further insights from the Reactor Safety Study, see Fleming (2021). Despite its successes, a variety of criticisms and unfavorable press releases led to NRC withdrawing support for PRA. It was not until the Three Mile Island Unit 2 (TMI-2) accident (Walker, 2004) and reviews of that accident (Kemeny et al., 1979; Rogovin et al., 1979), which chastised NRC for not using a tool that could have helped avoid the accident, that NRC returned to PRA. In the years that followed, the Commission issued a policy statement (US NRC, 1995) supporting 'risk-informed' regulation, PRA methods were further improved and extended, a consensus PRA standard was issued to assure PRA quality (ASME/ANS, 2009), and NRC issued guidance documents on PRA quality (US NRC, 2009).

PRA—Probability and consequences

PRA (Modarres, 2021) takes a different tack from that developed by AEC over the 1950–70 timeframe. Rather than a representative set of stylized scenarios, analyzed 'conservatively' to test the margin of safety systems, PRA attempts to model the plant realistically. Recall the risk triplet. PRA attempts to model all scenarios that could lead to core damage and release. It acknowledges that some single failures can be more likely than double failures and models all the interactions among system components, allowing their individual reliabilities to be used to calculate the overall system reliability. The supporting engineering calculations (e.g., thermal-hydraulics) are performed on a best-estimate basis rather than a conservative one. However, they must account for uncertainties in data and modeling.

One of the first industry-sponsored PRAs, the Indian Point Probabilistic Safety Study (Pickard, Lowe, and Garrick, Inc. et al., 1982) was instrumental in resolution of the Indian Point ASLB hearings on the risk from that plant (Palladino et al., 1985). Having been designed and built in the 1960s, these units had not been designed to withstand external events (such as earthquakes and fires) to the same degree as more modern plants. During the course of the PRA, improvements were proposed to reduce risks in three general areas—earthquakes, fires, and hurricanes. They included:

- The installation of a bumper between the control building and the superheater building of Unit 2 to dampen interactions in the event of an earthquake.
- The addition of alternate power cables for the component cooling water and charging pumps at Units 2 and 3 to increase the reliability of these pumps in case of fires.
- A modification of the technical specifications for the operation of Unit 2 to require plant shutdown in the event of a hurricane.

These improvements significantly reduced the likelihood of core melt at the Indian Point Units 2 and 3, and their cost effectiveness was recognized by the NRC as well as by the plant licensees. In a meeting of the U. S. Nuclear Regulatory Commission ([US NRC, 1984](#)), Frank Rowsome, Assistant Director for Technology of the NRC, stated that:

The [pre-PRA] mitigation conceptions, both those that were subject to contention [in the ASLB hearings on the safety of the plants] and those that had been developed in the [NRC] staff action plan...cost more than they were worth... The prevention improvements volunteered by the licensees were worth roughly a quarter of a billion dollars in averted risk, a whopping big value. Their cost ...was of the order of \$1 million or thereabouts, for about 100 to 1 value to cost ratio. In fact, if you count in the whole cost of the hearing and the inquiry and the PRAs and everything in the balance, the value accorded the fixes we found was about ten times the cost of the entire enterprise.

Over the next 20 years PRA models were developed for most plants by both the owners and the NRC. These models were used to identify risk outliers and improve them, optimize technical specifications, and to address specific regulatory issues. By 1986 the U.S. Department of Energy ([DOE, 1986](#)) submitted an application for the General Atomics modular high temperature gas-cooled reactor (MHTGR) with a safety case based on extensive use of its PRA ([Williams et al., 1989](#)). Some years later, NRC developed a similar approach known initially as the technology neutral framework ([Drouin et al., 2007](#); [ACRS, 2007](#)) that included parallel considerations of defense-in-depth as a means to protect against uncertainties in the PRA model.

Defense-in-depth

A paper, "On the Role of Defense in Depth in Risk-Informed Regulation," was issued earlier as an attachment to an ACRS letter report ([ACRS, 1999](#)). The letter stated that improved capability to analyze nuclear power plants as integrated systems is leading us to reconsider the role of defense-in-depth. Two different perceptions of defense-in-depth were identified. In one view (the "structuralist" view), defense-in-depth is considered to be the application of multiple and redundant measures to identify, prevent, or mitigate accidents to such a degree that the design meets the safety objectives. Until recently, this has been the general view taken by plant designers. The other view (the "rationalist" view) sees the proper role of defense-in-depth in a risk-informed regulatory scheme as compensation for inadequacies, incompleteness, and omissions of risk analyses.

As stated in the paper, the structuralist and rationalist models need not be in conflict. Both can be construed as a means of dealing with uncertainty. In the final analysis, they both depend on knowledgeable people discussing the risks and uncertainties, and ultimately agreeing on the provisions that must be made in the name of defense-in-depth.

The difference is that the structuralist model accepts defense-in-depth as the fundamental value, while the rationalist model would place defense-in-depth in a subsidiary role. Adopting a high-level structuralist view and a low-level rationalist view is a pragmatic approach to reconciling defense-in-depth with risk-informed regulation. There can be little doubt, however, that the rationalist model will ultimately provide the strongest theoretical foundation for risk-informed regulation. As more experience has been gained with the application of PRA in the design and regulation of nuclear power plants, when PRA models can adequately treat most of the phenomena of interest, the role of defense-in-depth can and should be changed to one of supporting the risk analyses. This transition will need to be supported by the development of subsidiary principles from which necessary and sufficient criteria could be derived.

At the present time, the traditional approach to licensing remains and applicants are free to temper it with risk-informed applications. However, a new generation of reactors is being developed including small modular reactors, micro-reactors, passive designs, and simplified designs. For many of these a simpler approach to licensing might be possible. NRC staff has been working with stakeholders to develop a vision and strategy for licensing the new designs. One key aspect is an extension of the MHTGR and NUREG-1860 approach laid out in an industry document that NRC may adopt ([NEI, 2019](#); [US NRC, 2018a](#); [ACRS, 2019](#)). This technology-inclusive, risk-informed, and performance-based methodology for informing the licensing basis and content of applications for non-light-water reactors marks the next evolution of a licensing approach that has been developed over the past 30 years. Its use is confined to three objectives: to select licensing basis events; to classify structures, systems, and components; and to assess the adequacy of defense-in-depth for new designs. The licensing basis events include AOs, design basis events, and beyond design basis events, all now defined unambiguously by the PRA frequency results. For classifying structures, systems and components, the paper extends and makes operational the concepts that were expressed earlier in NUREG-1860 ([Drouin et al., 2007](#)). They are selected from important risk contributors in the PRA, with special treatment assigned based on importance to risk. For defense-in-depth, the paper provides an operational structure for evaluation. It bridges the gap between frameworks as described in NUREG-1860 and NUREG/KM-0009 ([Drouin et al., 2016](#)), and viable regulatory actions. As discussed in [Fleming \(2021\)](#), the report ([NEI, 2019](#)) describes a defense-in-depth approach that includes probabilistic and deterministic assessment techniques using a combination of plant capabilities and programmatic controls. As part of the evaluation, each licensing basis event is evaluated to confirm that risk targets are met without exclusive reliance on a single element of design, single program, or single defense-in-depth attribute. One of the primary motivations of employing defense-in-depth attributes is to address uncertainties, including those that are reflected in the PRA estimates of frequency and consequence, as well as other uncertainties which are not sufficiently characterized for uncertainty quantification and are not amenable to sensitivity analyses. The designer is to convene an Integrated Decision Panel to make judgments involving quantitative and qualitative factors.

The effect of accidents on regulatory process

We consider three accidents at nuclear power plants that have had substantial impact on the design, operation, and regulation of nuclear plants in the U.S.: the Browns Ferry Fire in 1975 ([Gonzalez et al., 2014](#)), the Three Mile Island 2 accident in 1979, ([Walker, 2004](#); [Skillman and Rempe, 2021](#)), and the Fukushima earthquake and tsunami 2011 ([Miller et al., 2011](#); [Mizokami and Rempe, 2021](#)). As a result of these accidents, the NRC dramatically revised regulations and industry refined operating practices—e.g., fire protection requirements, the development of symptom-based procedures, a requirement for on-site simulators, and establishment of the Institute for Nuclear Power Operations (INPO). Following the Three Mile Island accident, there was a long delay in licensing plants in the regulatory review pipeline that burdened several utility companies with massive debt. The net effect of the response of the industry and NRC to these accidents has been a substantial improvement in the safety of our nuclear power plants. Additional accidents that impacted reactor design, operation, and regulation are described in other chapters ([Rempe, 2021a](#); [Sich, 2021](#)).

The Browns Ferry fire

The Browns Ferry fire ([Gonzalez et al., 2014](#); [Rempe, 2021a](#)) started on March 22, 1975 by a worker using a lit candle to check for air leaks around cable seals. It propagated quickly then continued to burn for many hours because plant personnel did not want to put water on an electrical fire. Before it ended, many of the engineered safety features were disabled. NRC published recommendations ([US NRC, 1976](#)), new guidance ([US NRC, 1977a](#)), and a new regulation, 10 CFR 50.48(b) in 1980. The approach was deterministic and tried to ensure safety margin to fire events ([US NRC, 1981](#)). However, many plants had to seek temporary exemptions because of specific design issues. Some of the fire-related issues were not resolved until recently as part of the Alternate Fire Protection Rule 10 CFR 50.48(c) which incorporates the National Fire Protection Association (NFPA) Standard NFPA 805 ([NFPA, 2001](#)) by reference, a risk-informed, performance-based standard.

The Three Mile Island accident

The Three Mile Island-2 PWR accident ([Walker, 2004](#)) began at 4:00 am on March 28, 1979 as a simple secondary system transient when pumps in the condensate polishing system tripped. Bypass valves that should have allowed continued feedwater flow failed to open. Due to the loss of a condensate flow path, the main feedwater pumps tripped, as they should. Unfortunately, the remaining system that could have provided feedwater, the auxiliary feedwater system, also failed because two valves in the lines to the steam generators were inexplicably left closed. Now, with no secondary heat removal, pressure in the primary system increased. The reactor tripped, but with no secondary cooling, pressure continued to rise causing a power operated relief valve to open. It failed to reclose, but because the control room indication was based on the demand signal to open the valve, it erroneously indicated closed. Because the valve had previously leaked, the operators failed to see the high downstream temperature as an alternative indication of valve position. So, because of multiple failures, the condition of the plant was masked to the operators, who did not realize that a small loss of coolant accident was in progress. This is exactly the sort of multiple failure situation that is modeled in PRA.

The plant was still in relatively good condition and had built-in capability to survive the accident. Unfortunately, when the pressurizer level dropped below the heaters and the system lost overpressure, the reactor coolant became saturated and a steam bubble developed in the hottest location in the system—at the outlet of the core in the top of the reactor vessel. The pressurizer was no longer an indicator of the volume of water in the system; its level began to rise as the steam bubble in the reactor vessel expanded. Fearful of over-filling the pressurizer and going ‘water solid’ the operators turned off the safety injection system, which was providing makeup water to ensure core cooling. (Actually, going water solid is a dangerous condition, because slight changes in temperature can lead to large pressure variations.) There were additional issues later, but the fate of the plant was already sealed.

Following the accident, there were a great many lessons learned and NRC issued a number of orders and short- and long-term plans. There were a number of reviews of the accident sponsored by the government and industry. Among them, the two most far-reaching were the President’s Commission Report ([Kemeny et al., 1979](#)) and the Rogovin Report ([Rogovin et al., 1979](#)) commissioned by the NRC. Both reports drew a similar overall conclusion: the primary problems were not with the equipment, but with management; fundamental changes are needed in the organization, procedures, practices, and attitudes of the industry and the NRC. Quoting the Kemeny Report:

We are convinced that if the only problems were equipment problems, this Presidential Commission would never have been created. The equipment was sufficiently good that, except for human failures, the major accident at Three Mile Island would have been a minor incident. But, wherever we looked, we found problems with the human beings who operate the plant, with the management that runs the key organization, and with the agency that is charged with assuring the safety of nuclear power plants... In the testimony we received, one word occurred over and over again. That word is “mindset”... they concentrated on equipment, assuming that the presence of operators could only improve the situation – they would not be part of the problem... [T]he belief that nuclear power plants are sufficiently safe grew into a conviction... The Commission is convinced that this attitude must be changed to one that says nuclear power is by its very nature potentially dangerous, and, therefore, one must continually question whether the safeguards already in place are sufficient to prevent major accidents. A comprehensive system is required in which equipment and human beings are treated with equal importance... We note a preoccupation with regulations... [O]nce regulations become as voluminous and complex as those regulations now in place, they can serve as a negative factor in nuclear safety... This Commission believes that it is an absorbing concern with safety that will bring about safety – not just the meeting of narrowly prescribed and complex regulations.

Both reviews found deficiencies in training, particularly with respect to understanding unusual conditions. They also found the emergency operating procedures deficient and confusing. Both the NRC and the industry had focused almost entirely on design, with little focus and little expertise in operations. The lessons from previous accidents did not result in new, clear instructions being passed on to the operators; there were precursors to this accident, but the operators and many others were unaware of them. Generic safety issues had been open for years. The lessons of WASH-1400 were forgotten and the NRC should put more emphasis on risk, by emphasizing those accident sequences that contribute significantly to risk. The design review can then focus on those systems that contribute to risk, identify weak points, and make improvements to eliminate them.

There were an enormous number of recommendations in the two reports. Rather than focus on all of those, here is a list of some of the many changes that came about in response to the accident:

- Symptom-based procedures organized to emphasize the most risk important response first. Earlier procedures were based on high level response to very specific events and did not help in complex situations or those that deviated from the stylized scenarios of the safety analysis.
- Improved monitoring of key accident parameters such as reactor water level, development of the safety monitor to support symptom-based procedures and grouping displays to better support operator needs.
- The establishment of realistic simulators at every plant. The models were improved to included details that operators would see, even if those were not crucial in safety analysis.
- Requiring a graduate engineer on shift as the Shift Technical Advisor, to provide oversight and advise the operating crew of unanticipated safety issues.
- The establishment of NRC resident inspectors at all plants.
- The establishment of INPO. It fulfilled many recommendations: the industry needs to take more ownership of safety, the industry should establish a training institute, and the industry should track, evaluate, and share operational experience.
- The establishment of a Technical Support Center separate from the control room both to minimize traffic in the control room and to provide guidance during unusual situations, and communications with vendors, regulators, and other experts.
- The establishment of the Office of Analysis and Evaluation of Operational Data at NRC to review operating experience and share important observations throughout the NRC.

Finally, quoting the Rogovin report's balancing of their criticism:

In an investigation like this, the very purpose of which is to focus on what went wrong and what needs changing, it is inevitable that less attention than is deserved will be given to what "went right"-the strong points in the system. Chief among these is the fact that the "defense in depth" concept worked to protect public health and safety. In spite of multiple equipment malfunctions, human failures, and the creation of conditions in the reactor and auxiliary buildings that were never contemplated in the design of the plant's safety systems, the utility and its engineering support staff were able to bring the system to a stable condition without releases of radioactive materials to the atmosphere that could have resulted in significant health effects to those living near the plant.

Thereafter, a massive response by industry, the national laboratories, and government greatly assisted the plant operator, Met Ed, both in bringing the plant to a safe shutdown and in establishing recovery operations. Over a thousand people, from reactor operators and health physics technicians to top executives from every corner of the industry, dropped their everyday work and went to the TMI site. Thousands more were active in performing supporting analyses and experiments, and in procuring and dispatching needed supplies.

The Fukushima accident

The Fukushima accident (Neureiter et al., 2014) occurred on March 11, 2011 when the Great East Japan Earthquake was followed by a massive tsunami that damaged the Dai-ichi nuclear power plant and wreaked havoc on Japan destroying property over a wide area and killing more than 15,000 people. At Dai-ichi, the operating Units 1, 2, and 3 were responding to a loss of offsite power and associated reactor trips, when the tsunami rolled over the site flooding some areas of Units 1, 2, 3 and 4 (Unit 4 was in an outage with all its fuel removed, so it required no cooling). The most important damage was the flooding of lower areas of the plants including the diesel generator and battery rooms causing a loss of all AC electrical power and leading to the loss of DC power, almost immediately in Units 1 and 2, and after about a day and a half in unit 3. The three operating reactors were BWR designs. Unit 1 included two passive emergency heat exchangers called the isolation condenser system. The shell side of each condenser could be replenished from outside the plant. Varied reasons for their failure and the inability of operators to restore isolation condenser cooling have been suggested in different accounts of the accident. Unit 2 had a turbine driven cooling system that was able to run for about 3 days. Unit 3 had two turbine driven cooling systems that continued to function for about a day and a half. At each operating unit, the loss of all core cooling led to fuel damage and subsequent release of fission radioactive materials and hydrogen. After fuel damage, it was important to vent the containment before catastrophic failure on over-pressure. A number of problems delayed venting. Units 1, 3, and 4 suffered structural damage from hydrogen explosions.

Working conditions were extremely difficult due to high temperatures, high radiation fields, lack of lighting, the need for bulky personnel protective equipment, and the failure of communication devices. Additionally, for weeks there were inadequate accommodations for sleeping, eating, and bathrooms, and workers could not communicate with family members to ascertain their safety following the tsunami. In these conditions, operators jury-rigged ways to inject water to cool damaged cores and limit the off-site health effects. As described below, numerous reports provide additional details of the accident progression at each unit.

Following the accident there were numerous investigation reports by the Japanese utility company, the Japanese government, and international government, academic, and industrial organizations. A long list is provided in the U.S. National Academy report (Neureiter et al., 2014). There were also articles and books by individuals who were on-site during the accident. We will focus here on the response in the U.S., by industry, NRC, and interested parties. The first report was by the ‘Near-Term Task Force’ (NTTF) established by the NRC to investigate implications for regulation in the U.S. They were given 90 days to complete their review and provide recommendations to the NRC. Their report (Miller et al., 2011) surprised many people by its thoroughness and the strength of its recommendations. After review of that report and discussions with the NRC staff, the ACRS (ACRS, 2011a) reported that,

While complete understanding of the Fukushima Dai-ichi accident will take many years, the NTTF Report and the staff’s recommended actions to be taken without delay are appropriately focused on lessons learned from what is currently known. We believe that none of the recommendations enumerated...will be negated, or rendered inappropriate, by the acquisition of new information. Hence, timely initiation of the staff’s recommended actions to be taken without delay, along with corresponding additions or modifications included herein, is appropriate.

The ACRS recommended specific expansion of a few of the NTTF recommendations. The staff described a three-tiered approach for addressing these issues, because it was not possible to do them all at once. They set priorities based on risk significance, the need for additional assessment, available resources and critical skills, dependence on resolution of higher tier results (ACRS, 2011b).

Over the next decade, NRC and industry took many actions that should help plants survive very rare events. The enhancements included: adding capabilities to maintain key plant safety functions following a large-scale natural disaster; updating evaluations on the potential impact from seismic and flooding events; providing new equipment to better handle potential reactor core damage events; and strengthening emergency preparedness capabilities. Combined, these actions enhance the likelihood that the nuclear industry and the NRC are prepared for the unexpected. Among the most important of these is the industry FLEX approach to provide backup equipment at plants and in regional supply centers, with rapid delivery capability to any plant in the nation, called SAFER. This equipment is provided with rapid hookup capability, now also installed in all plants and a set of mitigation strategies for using the equipment. Many details for these improvements can be found on the NRC’s public website (nrc.gov), by searching for Post-Fukushima Safety Enhancements there.

Summary

This chapter has described problems associated with developing regulations for a new industry. As the AEC embarked on developing a system of regulation, acting Chairman Libby provided a safety philosophy based on three goals—recognize all possible accidents, minimize the probability of an accident, and use a combination of containment and isolation to protect the public from the consequences of such an accident (Libby, 1956). The evolving regulatory process can be seen as a series of attempts to meet these goals, first by creatively applying engineering judgment, then by attempts to bound each criterion, and eventually finding a way to quantify each of them.

By the early 1970s, the AEC had established an extensive catalog of regulations and it began to publish a variety of guidance documents supporting those regulations. The Standard Review Plan provides guidance to the regulatory staff on conducting review of applications and an extensive set of Regulatory Guides provides applicants with approved methods and approaches for meeting the regulations.

In 1972, the AEC commissioned the Reactor Safety Study to estimate the probability of a severe reactor accident, something that had eluded its scientists and contractors for years. With its publication the Commission had, in principle, the tools to implement risk-informed regulation that accounted for both the probability and consequences of accidents. It took many years to gain confidence in this approach and, in 2020, the agency is on the cusp of making more extensive use of this approach (Bley and Malsch, 2021).

Regulations also evolved in response to operational events, including accidents. Three accidents discussed in this chapter had far-reaching impact on regulations and operating practice in the U.S. industry.

Glossary

Advisory Committee on Reactor Safeguards (ACRS) An advisory committee established by statute to advise the US Nuclear Regulatory Commission (formerly the Atomic Energy Commission) on matters of nuclear safety.

Backfitting A backfit occurs when the NRC changes its mind about the safety of a licensed facility and wants a plant to add additional protection; i.e., make modifications to installed equipment.

Code of Federal Regulations (CFR) Regulations promulgated by US government agencies. Commercial nuclear energy facilities are governed by 10 CFR Parts 1–199 promulgated by the US NRC.

General design criteria A set of broad plant design criteria defined in Appendix A to 10 CFR Part 50. The intent was to define criteria such that, if applicants could demonstrate that their design would meet them, it could expedite the licensing process and make it more predictable.

Generic safety issue Safety issues that arise during license application reviews by NRC or from other sources, such as accidents and requests from the public, that apply to all reactors or to a broad class of reactors and are not appropriate to resolve as part of a particular license application process.

Probabilistic risk analysis (PRA) An approach to safety analysis that identifies what can go wrong and quantifies the likelihood and consequences of each scenario. Risk of a facility is presented in terms of the probability of various consequences, including rankings of contributors to the risk and a formal treatment of uncertainty.

Regulatory guides Guidance documents from the NRC that provide applicants with acceptable ways to meet the regulations.

Rulemaking The process by which new regulations are introduced and processed by NRC, including being issued as formal changes or additions to 10 CFR Parts 1–199. The process is governed by NRC Management Directive 6.3.

US Nuclear Regulatory Commission (NRC) The body established by the Atomic Energy Act, as amended, to regulate civilian applications of nuclear power in the United States (formerly the Atomic Energy Commission).

Introduction

US regulations for commercial nuclear facilities are issued by the US Nuclear Regulatory Commission (NRC) and tabulated in Title 10 Parts 1–199 of the US Code of Federal Regulations (GPO 2019, 2020), as discussed in Bley and Malsch (2021). These regulations were initiated under the US Atomic Energy Commission (AEC). Harold Price, an AEC lawyer, was named to head a task force on regulation at the AEC in 1954. The task force laid out a plan to organize all licensing activities in one office, rather than the then current division of the responsibilities among multiple offices. The Commission approved the plan and Price headed up the new office; he would remain the agency's chief regulator until his departure in 1971. His group was devising a scheme of regulation from scratch. They had to decide what kinds of production and utilization facilities would need to be licensed, because the Atomic Energy Act of 1954 left such details up to the AEC. Available guidance indicated that regulation should be as minimal as would be consistent with protecting the health and safety of the public (Bley and Malsch, 2021). Regulations needed to be clear, providing the necessary legal, safety, and technical issues to protect the public, and be sufficiently flexible for a rapidly developing industry—a difficult task. Nevertheless, they issued key rules during 1955 and early 1956. For example, they provided a draft rule for the licensing of reactor operators in 1955 (Mazuzan and Walker, 1984).

This section provides a list of all the relevant parts of the regulations with some explanation of how they were developed.

Organization of Title 10 of the US Code of Federal Regulations (CFR)

The many parts of 10 CFR 1–199 are tabulated in [Table 1](#). The most directly relevant parts for commercial nuclear power reactors are:

- Part 20—Standards for protection against radiation, which describe the requirements for protecting workers and the public, as well as associated administrative requirements.
- Part 50—Domestic licensing of production and utilization facilities and describes the ‘two-step’ licensing process used for most existing plants, i.e., first a Construction Permit, later followed by an Operating License for a specific power plant.
- Part 51—Environmental protection regulations for domestic licensing and related regulatory functions.
- Part 52—Licenses, certifications, and approvals for nuclear power plants, which describes the optional certification and licensing process developed to support hoped for standardization of plant designs. Full implementation of Part 52 would involve design certifications, early site permits (ESPs), and combined licenses (COLs). A first step would be a design certification that approves a power plant design expected to be built at multiple sites. A prospective owner may obtain an ESP, which approves of a prospective site for an enveloped range of potential designs; with an ESP, the owner can later construct any certified design that fits within the approved envelop, without re-review of site suitability. The owner may also apply for a COL. The COL gives approval both to construct and to operate the facility, with the latter conditioned on satisfaction of a set of license conditions called acceptance criteria. As described by [Ray \(2021\)](#), Part 52 includes the flexibility to obtain an ESP with or without a design certification, and a COL with or without either a design certification or an ESP.

A rulemaking initiative began in 2020 that should harmonize Parts 50 and 52 such that the requirements of the two rules are synchronized ([US NRC, 2019a](#)).

- Part 53 does not yet exist. The NRC staff has begun work on the new Part 53 and plans to issue an Advanced Notice of Rule-making late in 2020 ([US NRC, 2020a,b](#)). A public meeting with the Advisory Committee on Reactor Safeguards (ACRS) was held on July 20, 2020 ([ACRS, 2020](#)). The new rule had been essentially directed by Congress ([US Public Law, 2019](#)) and is expected to apply to non-LWR designs that opt to use an approach based on the technology-inclusive, risk-informed, and performance-based methodology for informing the licensing basis and content of applications for non-light-water reactors. The methodology is used to accomplish three objectives—to select licensing basis events; to classify structures, systems, and components; and to assess the adequacy of defense-in-depth ([NEI, 2019](#); [US NRC, 2018a,b](#); [ACRS, 2019](#); [Bley and Malsch, 2021](#); [Fleming, 2021](#)).
- Part 54—Requirements for renewal of operating licenses for nuclear power plants.
- Part 55—Requirements for operator licenses.
- Part 100—Reactor site criteria (which was discussed in Section 4.13).

The regulations for licensing commercial nuclear power plants fall under 10 CFR Parts 50 and 52 (and, possibly in the future Part 53). These regulations are similar, so we use Part 50 as an example, which includes the following sections:

- General Provisions—Sections 1–9
- Requirement of License, Exceptions—Sections 10–13
- Classification and Description of Licenses—Sections 20–23
- Applications for Licenses, Certifications, and Regulatory Approvals ...—Sections 30–39
- Standards for Licenses, Certifications, and Regulatory Approvals—Sections 40–49
- Issuance, Limitations, and Conditions of Licenses and Construction Permits—Sections 50–68
- Inspections, Records, Reports, Notifications—Sections 69–76
- US/IAEA Safeguards Agreement—Section 78
- Transfers of Licenses—Creditors’ Rights—Surrender of Licenses—Sections 80–83
- Amendment of License or Construction Permit at Request of Holder—Sections 90–92
- Revocation, Suspension, Modification, Amendment of Licenses and Construction Permits, Emergency Operations by the Commission—Sections 100–103
- Backfitting—Section 109
- Enforcement—Sections 110–111
- Additional Standards for Licenses, Certifications, and Regulatory Approvals—Sections 120–155

Other parts of 10 CFR 1–199 apply legal, procedural, and process issues with which the owner must comply.

Broad requirements of Title 10 of the Code of Federal Regulations Parts 1–199

Generally, the broad requirements incorporated into the regulations were anticipatory in nature and intended to reflect good practice. They usually came about in response to issues raised by the ACRS, the staff, and other stakeholders and the development of most were discussed in [Bley and Malsch \(2021\)](#). A list of the most significant regulations would include:

- 50.34 Contents of applications; Technical Information

Table 1 Title 10 Code of Federal Regulations Parts 1–199.

<i>Title 10 Code of Federal Regulations Parts 1–199</i>	
Part 1	Statement of Organization and General Information
Part 2	Agency Rules of Practice and Procedure
Part 4	Nondiscrimination in Federally Assisted Programs or Activities Receiving Federal Financial Assistance from the Commission
Part 5	Nondiscrimination on the Basis of Sex in Education Programs or Activities Receiving Federal Financial Assistance
Part 7	Advisory Committees
Part 8	[Reserved]
Part 9	Public Records
Part 10	Criteria and Procedures for Determining Eligibility for Access to Restricted Data or National Security Information or an Employment Clearance
Part 11	Criteria and Procedures for Determining Eligibility for Access to or Control over Special Nuclear Material
Part 12	Implementation of the Equal Access to Justice Act in Agency Proceedings
Part 13	Program Fraud Civil Remedies
Part 14	Administrative Claims under Federal Tort Claims Act
Part 15	Debt Collection Procedures
Part 16	Salary Offset Procedures for Collecting Debts Owed by Federal Employees to the Federal Government
Part 19	Notices, Instructions and Reports to Workers: Inspection and Investigations
Part 20	Standards for Protection Against Radiation
Part 21	Reporting of Defects and Noncompliance
Part 25	Access Authorization
Part 26	Fitness for Duty Programs
Part 30	Rules of General Applicability to Domestic Licensing of Byproduct Material
Part 31	General Domestic Licenses for Byproduct Material
Part 32	Specific Domestic Licenses to Manufacture or Transfer Certain Items Containing Byproduct Material
Part 33	Specific Domestic Licenses of Broad Scope for Byproduct Material
Part 34	Licenses for Industrial Radiography and Radiation Safety Requirements for Industrial Radiographic Operations
Part 35	Medical use of Byproduct Material
Part 36	Licenses and Radiation Safety Requirements for Irradiators
Part 37	Physical Protection of Category 1 and Category 2 Quantities of Radioactive Material
Part 39	Licenses and Radiation Safety Requirements for Well Logging
Part 40	Domestic Licensing of Source Material
Part 50	Domestic Licensing of Production and Utilization Facilities
Part 51	Environmental Protection Regulations for Domestic Licensing and Related Regulatory Functions
Part 52	Licenses, Certifications, and Approvals for Nuclear Power Plants
Part 53	[Reserved]
Part 54	Requirements for Renewal of Operating Licenses for Nuclear Power Plants
Part 55	Operators' Licenses
Part 60	Disposal of High-Level Radioactive Wastes in Geologic Repositories
Part 61	Licensing Requirements for Land Disposal of Radioactive Waste
Part 62	Criteria and Procedures for Emergency Access to Non-Federal and Regional Low-Level Waste Disposal Facilities
Part 63	Disposal of High-Level Radioactive Wastes in a Geologic Repository at Yucca Mountain, Nevada
Part 70	Domestic Licensing of Special Nuclear Material
Part 71	Packaging and Transportation of Radioactive Material
Part 72	Licensing Requirements for the Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste, and Reactor-Related Greater than Class C Waste
Part 73	Physical Protection of Plants and Materials
Part 74	Material Control and Accounting of Special Nuclear Material
Part 75	Safeguards on Nuclear Material—Implementation of Safeguards Agreements between the United States and the International Atomic Energy Agency
Part 76	Certification of Gaseous Diffusion Plants
Part 81	Standard Specifications for The Granting of Patent Licenses
Part 95	Facility Security Clearance and Safeguarding of National Security Information and Restricted Data
Part 100	Reactor Site Criteria
Part 110	Export and Import of Nuclear Equipment and Material
Part 140	Financial Protection Requirements and Indemnity Agreements
Part 150	Exemptions and Continued Regulatory Authority in Agreement States and in Offshore Waters under Section 274
Part 160	Trespassing on Commission Property
Part 170	Fees for Facilities, Materials, Import and Export Licenses, and Other Regulatory Services under The Atomic Energy Act of 1954, As Amended
Part 171	Annual Fees for Reactor Licenses and Fuel Cycle Licenses and Materials Licenses, including Holders of Certificates of Compliance, Registrations, and Quality Assurance Program Approvals and Government Agencies Licensed by the NRC
Parts 172–199	[Reserved]

- 50.36 Technical Specifications (Safety License Conditions)
- 50.36a Technical Specifications on Effluents from Nuclear Power Reactors
- 50.69 Risk-Informed Categorization and Treatment of Structures, Systems and Components for Nuclear Power Reactors
- Appendix A to Part 50—General Design Criteria for Nuclear Power Plants
- Appendix B to Part 50—Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants

Particular issues that extended the regulations

A number of regulations were reactive, issued in response to concerns about specific issues. Some of these issues arose during NRC staff and ACRS reviews of license applications, some were identified as a result of operational events and accidents, and some were identified from the results of safety research. Some were relatively simple to address, others eventually arose from or led to investigative hearings. For example, 50.46 and 50.46(a) address emergency core cooling systems and were issued originally in response to research questioning the adequacy of then current systems and a long and contentious rule-making hearing.

Many of the issues that extended the regulations originated as so-called unresolved safety problems. The origin of this concept was in the earliest license application reviews in which the AEC staff argued that construction could continue when they found that “there was reasonable assurance that the reactor could be operated safely or at least that any unresolved safety problems could be mitigated over the intervening construction period ... Excessive caution, though ... might also have a negative impact on development of the industry. The problem was to find the appropriate balance despite many unanswered questions about atomic energy” (Mazuzan and Walker, 1984). The issues that were specific to the design under review were straightforward to address. Others really applied to all reactors or to a broad class of reactors and were not appropriate to resolve as part of the license application process. These became known as generic safety issues. More pressing design-specific issues received staff attention, while others did not. Eventually, the list of unresolved generic safety issues grew to an embarrassing length. The Commission finally directed the staff to develop a program to resolve these generic safety issues and a 1977 amendment to the Energy Reorganization Act of 1974 included a new Section 210 (US NRC, 2015):

The Commission shall develop a plan providing for specification and analysis of unresolved safety issues relating to nuclear reactors and shall take such action as may be necessary to implement corrective measures with respect to such issues. Such plan shall be submitted to the Congress on or before January 1, 1978 and progress reports shall be included in the annual report of the Commission thereafter.

The NRC staff proposed a generic issues program planned to identify all existing generic issues, set priorities among them, and lay out plans for resolving the most important of them that identified the associated estimated costs (US NRC, 1978). They initially ranked the issues based on importance into one of four categories from significant to of little or no importance using engineering judgment (US NRC, 2011a,b). This was followed by developing a semi-quantitative approach using results from probabilistic risk assessment (PRA) (Bley and Malsch, 2021; Dube, 2021; Fleming, 2021; Modarres, 2021) and later by a more fully quantitative use of PRA to identify the projected risk reduction by resolving each generic issue, along with an estimate of the costs. Following the accident at Three Mile Island Unit 2 (Bley and Malsch, 2021; Skillman and Rempe, 2021; Walker, 2004) many new generic issues were identified (US NRC, 2011a), and the NRC staff requested Commission approval to use the new methodology (US NRC, 1981). After discussion and revision the Commission approved its use (US NRC, 1983).

A summary of some of the regulations that were issued in response to concerns about specific issues is provided in the following list:

- 10 CFR 50.44 Combustible Gas Control
- 10 CFR 50.46 Acceptance Criteria for Emergency Core Cooling Systems for Light-Water Nuclear Power Reactors
- 10 CFR 50.46a Acceptance Criteria for Reactor Coolant System Venting Systems
- 50.47 Emergency Plans
- 50.48 Fire Protection
- 50.49 Environmental Qualification of Electric Equipment Important to Safety For Nuclear Power Plants.
- 50.61 Fracture Toughness Requirements for Protection Against Pressurized Thermal Shock Events.
- 50.61a Alternate Fracture Toughness Requirements for Protection Against Pressurized Thermal Shock Events
- 50.62 Requirements for Reduction of Risk from Anticipated Transients without Scram (ATWS) Events for Light-Water-Cooled Nuclear Power Plants
- 50.63 Loss of All Alternating Current Power (Station Blackout)
- 50.150 Aircraft Impact Assessment
- 50.155 Mitigation of Beyond-Design-Basis Events
- Appendix E to Part 50—Emergency Planning and Preparedness for Production and Utilization Facilities
- Appendix G to Part 50—Fracture Toughness Requirements
- Appendix H to Part 50—Reactor Vessel Material Surveillance Program Requirements
- Appendix K to Part 50—ECCS Evaluation Models
- Appendix R to Part 50—Fire Protection Program for Nuclear Power Facilities Operating Prior to January 1, 1979

Legal, procedural, and processes issues

Legal, procedural and process issues are addressed primarily in 10 CFR Part 2, which addresses how public hearings on license applications, contested enforcement actions (like license suspensions), and monetary civil penalties are conducted, and how members of the public may ask the NRC to revoke or suspend licenses. But 10 CFR Part 50 also includes some process-related provisions, e.g., provisions addressing license transfers (50.80), financial security interests (50.81), license termination (50.82), decommissioning (50.83), grounds for license termination (50.100–50.103) and grounds for criminal prosecution for willful violations of the Atomic Energy Act and NRC regulations (50.110–50.111). The NRC may, by itself, initiate legal proceedings to suspend, revoke and amend licenses, and to impose monetary civil penalties for violations of its regulations, but alleged criminal violations must be referred to the US Department of Justice for consideration of criminal prosecution.

Summary

NRC regulations were developed from a blank slate following passage of the Atomic Energy Act of 1954. They are tabulated in 10 CFR Parts 1–199. Rules were developed to address broad requirements that were anticipatory in nature and intended to reflect good practice; to address particular issues in response to accidents, generic safety issues, and new research; and to fulfill legal, procedural and process issues. New regulations are introduced through the rulemaking process ([US NRC, 2019b](#)).

Glossary

Advisory Committee on Reactor Safeguards (ACRS) Independent Advisory Committee to the US Nuclear Regulatory Commission that is statutorily mandated by the Atomic Energy Act of 1954, as amended.

Atomic Safety and Licensing Board (ASLB) Independent trial level adjudicatory body of the NRC. Public hearings for individual applications are typically conducted by three designated panel members.

Combined License (COL) Authorization for a licensee to construct and operate a facility using a certified standard design.

Construction Permit (CP) Authorization for a licensee to construct a facility.

Design Certification (DC) A Commission approval, issued under subpart B of 10 CFR Part 52, of a standard design for a nuclear power facility. This design may be referred to as a certified standard design.

Design Control Document (DCD) Document submitted by the applicant that provides information to support the NRC's approval and certification of a standard design, under the provisions of 10 CFR Part 52.

Early Site Permit (ESP) A Commission approval, issued under subpart A of 10 CFR Part 52, for a site for one or more nuclear power facilities. The early site permit will address site safety issues, environmental protection issues, and plans for coping with emergencies, independent of the review of a specific nuclear plant design.

Final Safety Analysis Report (FSAR) Document submitted by applicant that provides information to support the US NRC safety evaluation of a proposed facility. It is based on the finalized detailed design of the facility, and it must periodically be updated throughout the life of the facility.

Operating License (OL) Authorization for a license to operate a facility.

Preliminary Safety Analysis Report (PSAR) Document submitted by applicant that provides information to support the US NRC safety evaluation of a proposed facility. It is based on the preliminary design of a facility and limited to use in the two-step 10 CFR Part 50 process.

Safety Evaluation Report (SER) NRC document summarizing the anticipated effect of the proposed application on public health and safety.

Standard Design Approval (SDA) An NRC staff approval, issued under subpart E of 10 CFR Part 52, of a standard design for a nuclear power reactor of the type described in 10 CFR 50.22. The approval may be for either the design for the entire reactor facility or the design of major portions thereof.

Introduction

As described in detail, US Federal law ([U.S. Government Publishing Office, 2019](#)) requires that an operating license (OL) be issued by the US Nuclear Regulatory Commission (NRC) specifically for each commercial nuclear power plant prior to its entering service. Issuance of the license is based on both safety and environmental impact reviews of the proposed plant, and the initial term of the license is limited to 40 years. Broadly, there are two alternative pathways available for obtaining an OL, and each pathway requires one or more prior approvals to be obtained before the plant can be constructed and the OL can be issued.

Requirements for the first alternative pathway are set forth in 10 CFR Part 50. This provides for a two-step process to obtain an OL (see [Fig. 1](#)). First, prior to commencing construction, a Construction Permit (CP) must be obtained by the operator/licensee based on submittal and review of a Preliminary Safety Analysis Report (PSAR). Then, as construction is underway, an OL must be sought based on submittal and review of a Final Safety Analysis Report (FSAR), and the OL must be issued prior to fuel loading.

Fig. 1 10 CFR Part 50 licensing process.

Fig. 2 10 CFR Part 52 licensing process.

Since 1989, and as updated in 2007, a second alternative pathway has been provided in 10 CFR Part 52 (see Fig. 2). For those plants which incorporate a certified standard design, as described in a specified design control document (DCD), this alternative provides for a combined license (COL) to be obtained in a single step prior to commencing construction. Since the DCD can be referenced by multiple COL applicants, this second alternative pathway allows the cost of the design and its certification ultimately to be recovered from multiple plant owners. More importantly, it promotes standardization of the certified design, thus reducing plant OL uncertainty and the associated financial risk to the plant owner. Design certification (DC) does require significant up-front investment by the design vendor prior to sale of the certified design to plant owners following which operator/licensees then can apply for their respective COLs. The risk of recovering this required up-front investment is a significant hurdle for the design vendor. (Note: Plant ownership may be shared among several entities. The plant operator/licensee is limited to a single entity which usually also is one of the plant owners.)

Thus, under the Part 50 two-step process the plant owner bears more financial risk due to licensing uncertainty, which remains until the OL is issued to the operator/licensee following completion of construction, than it does under the Part 52 one-step process where the certified design vendor has separately obtained the certification for use of a standard plant design. However, the certified design vendor may have to bear the entire risk of the investment required to obtain DC prior to its first sale to a plant owner. To summarize, Part 52 effectively allows transfer of a portion of a plant owner's investment risk under Part 50 to the design vendor. Although this can become a major burden, a successful design vendor can market a DC to multiple plant owners.

Instead of design certification, a standard design approval (SDA) may be obtained for a new design and then referenced in either a Part 50 CP application or in a Part 52 COL application. An SDA does not provide the regulatory finality of a design certification, but it can cover a lesser design scope and require less initial investment, while resolving selected regulatory issues.

Either the two-step Part 50 CP/OL pathway or the one-step Part 52 COL pathway can be preceded by an Early Site Permit (ESP), as described in 10 CFR Part 52, Subpart A. The optional addition of an ESP to a plant development allows site-related matters to be addressed and decided prior to proceeding further with plant investment, and separately from obtaining either the CP or COL. However, obtaining an ESP prior to taking other licensing actions can add to the total time required.

Finally, regardless of the alternative pathway chosen, a comprehensive assessment of the environmental impact of plant construction and operation is separately required.

Current alternatives for licensing commercial nuclear power plants

Plant license application *not* based on certified standard design—10 CFR Part 50

If a proposed plant does not include a standard design which has been certified pursuant to 10 CFR 52, Subpart B, then the two-step licensing process described in 10 CFR Part 50 is required to be followed. More than 100 operating nuclear plants have used this licensing process, and its advantages include that it does not require as much investment in design development prior to obtaining the permit required to begin plant construction. Its disadvantages include that design development following CP issuance lacks the standardization of a certified design, and there is the potential for contested public hearings being required at both the CP and OL approval steps.

Principal elements of this process are as follows:

Submittal and review of the PSAR

10 CFR 50.34 describes in subsection (a) the minimum information required to be provided to support issuance of a CP. The information provided includes a description of the preliminary design, a safety assessment of the site and a safety assessment of the proposed plant.

Public meetings

An initial public meeting is held by the NRC upon submittal of the plant license application. A subsequent public hearing and findings by the Atomic Safety and Licensing Board (ASLB) is also required prior to issuance of the CP. A second public hearing is held prior to issuance of the OL only if its issuance is contested. (The ASLB conducts hearings and reaches findings relative to compliance with all regulatory requirements as a legal proceeding. Parties may then appeal findings to a separate Atomic Safety and Licensing Appeals Board.)

Elements of NRC safety review

The NRC review of safety analyses follows a standard review plan (SRP) applicable to the reactor type. For light water reactors, the SRP is provided in NUREG-0800. A review is also conducted by the NRC's independent Advisory Committee on Reactor Safeguards (ACRS). When the NRC completes its review, it issues a safety evaluation report (SER) summarizing the anticipated effect of the proposed plant on public health and safety.

Elements of NRC environmental review

In accordance with requirements of the National Environmental Protection Act, a full environmental impact statement (EIS) must be submitted and reviewed, relative to potential impacts and benefits of the proposed plant, prior to issuance of the CP. Regulatory requirements for the environmental review are provided in 10 CFR Part 51. (A supplemental EIS, addressing any changes which occurred following issuance of the CP, must also be submitted and reviewed prior to issuance of the OL.)

Construction permit issuance—Step one completed

At this point, following issuance of the CP, construction may commence. Typically, design details not previously completed are then finalized as necessary in advance of affected equipment procurement and as required to support ongoing construction. Deferral of investment in completing these design details until following CP issuance is an advantage of using the two-step 10 CFR Part 50 licensing process and avoids placing this investment at risk earlier in the process. Also, it allows the design details to reflect site specific (e.g., seismic, flooding, etc.) characteristics as well as the current selected equipment detailed information.

While use of the two-step licensing process allows deferral of investment in detailed design, it does not preclude use of existing designs, as appropriate, including designs certified in accordance with 10 CFR 52, Subpart C, standard designs approved in

accordance with 10 CFR 52, Subpart E, and designs used in plants previously approved under Part 50. The disadvantage of the two-step licensing process is that the first step does not authorize operation of the completed plant, and this may therefore be contested at the second step.

Submittal of final safety analysis report (FSAR)

The FSAR is submitted based on the finalized detailed design and in support of the second step, which is issuance of the OL. Information required to be included in the FSAR is provided in subsection (b) of 10 CFR 50.34.

Following issuance of the OL, the FSAR must periodically be updated throughout the life of the plant in accordance with 10 CFR 50.71(e). Guidance for this is provided in Regulatory Guide 1.181.

Operating license issuance—Step two completed

The OL is issued for an initial period of 40 years and is subject to renewal in 20 year increments.

Standard design certification—10 CFR Part 52, subpart B

The vendor of a new plant design must decide whether to pursue its development independently of prospective plant owners to the point that the design has been certified, or to develop the design with support from prospective plant owners. In the latter case, a design vendor/plant owner partnership can take the form of the two-step 10 CFR Part 50 process described above, in which the plant operator/licensee seeks a CP and then an OL, supported throughout by the plant design vendor. The completed design can then subsequently be certified for future use at other plants. Alternatively, prospective plant owners can support the plant design vendor as it pursues a DC and separately pursue the one-step 10 CFR Part 52 process described below, in which the plant operator/licensee seeks a COL based on the certified standard design.

Each standard DC requires a notice and comment rulemaking which is conducted in response to an application submitted by the design vendor. (The NRC may also elect to hold a legislative-style hearing to review comments received.) The DC review does not address site-specific design features, operational programs and environmental impacts of building the design at a particular site. Through 2019, DC has been finalized for five designs (As of August 2019, (NRC, 2019a), the NRC has issued the following design certifications: [Advanced Boiling Water Reactor \(ABWR\)](#); [ABWR Design Certification Rule \(DCR\) Amendment](#); System 80+; [Advanced Passive 600 \(AP600\)](#); [Advanced Passive 1000 \(AP1000\)](#); [Economic Simplified Boiling-Water Reactor \(ESBWR\)](#). A proposed rule for certification of the [Advanced Power Reactor 1400 \(APR1400\)](#) was issued in May 2019).

The certification is held by the design vendor and has an initial term of 15 years, which may be renewed. All major design features must be covered by the certification, and the required contents of the application are specified in 10 CFR 52.47. Sufficient detail is required to reach a final conclusion that there is reasonable assurance of adequate protection of the public health and safety and of the environment. As for the first step of the 10 CFR Part 50 process, a public hearing is required, and the design, when certified, must be as described in detail in the DCD referenced in the NRC rule.

If the certification is sought for an existing or evolutionary design, additional design development or testing prior to certification may not be required. However, advanced designs will require significant design development and may require testing to verify important design assumptions, either prior to certification or as a condition of certification. The NRC states that the design must be “essentially complete” in order to be certified.

The complete design description in the DCD is categorized as Tier 2 information, and it is equivalent to the information contained in a Part 50 FSAR. DCD Tier 2 information is approved, but it is not certified. A procedure is provided to allow changes to Tier 2 information without prior approval by the NRC, provided the change meets specific criteria. However, the DCD also includes select information which is categorized as Tier 1 and which is based entirely on the Tier 2 information. Due to its safety significance, Tier 1 information cannot be changed, or deviated from, except by first revising the rule which established the DC.

A third category of DCD information is Tier 2*. Due to its safety significance similar to Tier 1 information, Tier 2* information does require NRC approval prior to making a change, but the approval does not require a revision of the DC rule since it has not been certified as is Tier 1 information. The Tier 2* category exists in order to allow some added flexibility.

Tier 1 information in the DCD also provides the basis for, and includes, required inspections, tests, analyses and acceptance criteria (ITAAC) which must be satisfied prior to fuel loading. ITAAC include design acceptance criteria (DAC) which provide the processes and acceptance criteria for completing design detail which was not complete at the time of certification. To some extent, investment in design and testing can be deferred beyond certification by increasing use of ITAAC, including DAC, but this increased use reduces the certainty in what will ultimately be necessary to demonstrate that requirements have been met in order to allow fuel loading.

In all cases, a probabilistic risk assessment, including uncertainties, is required as part of the DC application. A framework and guidance is provided by NUREG-1860.

The investment in design detail required to obtain a standard design certification grows significantly as the departure from previously licensed designs increases. A standard design certification is valid for inclusion in a COL application for an initial term of 15 years, and this may be renewed.

Plant license application based on certified standard design—10 CFR Part 52, subpart C

If a proposed plant does use a vendor's standard design which has been certified pursuant to 10 CFR Part 52, Subpart C, then the one-step licensing process described in Subpart C may be followed by the plant operator/licensee to obtain a combined license (COL). That is, the separate CP and OL steps required in 10 CFR Part 50 are combined into a single step. The COL is a combined CP and conditional OL, it is issued for an initial term of 40 years, and the COL is subject to renewal. (The OL is conditional based on demonstrating that all requirements of the COL have been met prior to fuel loading.) Through 2019, COLs have been issued for eight sites (As of August 2019 ([NRC, 2019b](#)), the NRC has issued the following COLs: Detroit Edison Company for the Fermi Unit 3 ESBWR; Duke Energy Florida, LLC (DEF) for the Levy Nuclear Plant, Units 1 and 2 AP1000s; Dominion Virginia Power (Dominion) for the North Anna, Unit 3 ESBWR; Nuclear Innovation North America, LLC (NINA) for the South Texas Project, Units 3 and 4 ABWRs; Florida Power & Light Company (FPL) for the Turkey Point, Units 6 and 7 AP1000s; South Carolina Electric & Gas (SCE&G) for the Virgil C. Summer, Units 2 and 3 AP1000s; Southern Nuclear Operating Company (SNC) for the Vogtle, Units 3 and 4 AP1000s; and Duke Energy for the William States Lee III, Units 1 and 2 AP1000s. Per [NRC \(2019c\)](#), only the Fermi Unit 3, North Anna Unit 3, Vogtle Units 3 and 4, and William States Lee 1 and 2 COLs have not been terminated).

Principal elements of this process are as follows:

Submittal and review of the COL application (COLA)

Requirements concerning information to be included in the COLA are provided by 10 CFR Part 52.79 and associated guidance is provided in Regulatory Guide 1.206. In addition, design specific review standards may be created by the NRC to expedite the application submittal and review process. For multiple COLAs using the same certified design and submitted by multiple plant owners, the NRC encourages the use of what is referred to as a design-centered review approach to facilitate standardization of applicant reviews. (i.e., Multiple COL applicants form a design center and jointly interface with the NRC on design matters in common.) COLA reviews may proceed concurrently with review of a referenced DC application and do not need to wait until the DC rule is issued.

Public meetings

An initial public meeting is held by the NRC upon submittal of the plant license application. A subsequent public hearing and findings by the ASLB is also required prior to issuance of the COL. There is an opportunity for a hearing prior to authorization of operation of a completed facility, but at this point a petitioner must first show that the plant has not met, or will not meet, the acceptance criteria for operation established in the COL.

Elements of NRC safety review

The NRC review of safety analyses follows a standard review plan (SRP) applicable to the reactor type. For light water reactors, the SRP is provided in NUREG-0800. A review is also conducted by the NRC's independent ACRS. As in the case of a Part 50 review, when the NRC completes its review, it issues a SER summarizing the anticipated effect of the proposed plant on public health and safety.

Elements of NRC environmental review

To the extent that they have not been resolved in an earlier ESP approval for the plant site, environmental issues must be addressed in an environmental report as described above for the 10 CFR Part 50 process.

Combined license issued—Construction may commence

COL issuance authorizes construction of the plant, and it also authorizes operation subject to NRC approval of ITAAC compliance. ITAAC, including DAC, are provided in the referenced design certification, in any referenced ESP, and they are also developed during the COL review in accordance with 10 CFR Part 52.80 to verify that the facility has been constructed in accordance with its certified design.

Because the certification necessarily requires sufficient design detail to support concurrent approval of both construction and operation, changes to this detail may become necessary as construction proceeds. This includes changes to information requiring a rule change (Tier 1) or prior NRC approval (Tier 2*). Processing resulting amendments to the COL and DCD can delay construction, and the NRC has therefore implemented a preliminary amendment request procedure to reduce this potential impact. However, changes can remain a burden, especially for the initial applications of a design certification.

Inspections, tests, analyses and acceptance criteria met—Operation may commence

ITAAC, including DAC, can be established as part of: (1) design certification, (2) the optional ESP approval and (3) the COL approval. The NRC must review and accept in accordance with 10 CFR Part 52.103(g) that ITAAC have been met prior to affected structures, systems and equipment being considered operable for purposes of fuel loading or power production. This requires a public hearing near completion of plant construction.

The FSAR submitted in the COLA is updated at the time operation is authorized and it is maintained during the plant life, the same as for a FSAR submitted in support of a Part 50 OL.

Standard design approval (not certification)—10 CFR Part 52, subpart E

SDA, as described in 10 CFR Part 52, Subpart E, provides for NRC staff review and conclusions on a proposed design, or on only portions thereof. When referenced in subsequent Part 50 or Part 52 licensing applications, the SDA is not binding to the same extent as is a certified standard design. However, it may require far less investment and time to obtain, and it can therefore be a valuable part of a staged licensing process. As of August 2019, SDAs (previously termed to as final design approvals) have been finalized for all of the designs certified by the NRC.

Although detailed procedures may differ, the SDA may be considered comparable to the Vendor Design Review process of the Canadian Nuclear Safety Commission and Generic Design Assessment process of the United Kingdom Office for Nuclear Regulation insofar as it provides for clear and early feedback on potential licensing and safety issues. However, because SDA lacks the certainty of DC, it has not been favored as a licensing path. SDA applications are required to include information as described in 10 CFR Part 52.137.

Early site permit (ESP) approval prior to submittal of license application—10 CFR Part 52, subpart A

An optional ESP resolves issues of site suitability (including security issues), environmental impact (including consideration of alternative sites) and emergency planning. It includes a plant parameter envelope which is intended to bound actual plant designs which could be proposed using either the two-step Part 50 or one-step Part 52 licensing processes following ESP approval. Because it resolves issues of site suitability in accordance with the finality provisions of 10 CFR Part 52.39(a), it does require its own public hearing. The permit may be granted for a period of 10 to 20 years prior to plant licensing, and it is subject to renewal. Through 2019, ESPs have been finalized for four sites (Per [NRC \(2019d\)](#)), the NRC has issued the following ESPs for the following applicants: Clinton ESP Site for Exelon Generation Company, LLC; Grand Gulf ESP Site for System Energy Resources Inc.; North Anna ESP Site for Dominion Nuclear North Anna, LLC; Vogtle ESP Site for Southern Nuclear Operating Company; and PSEG Site for PSEG Power, LLC, and PSEG Nuclear, LLC (PSEG). The NRC is reviewing the ESP applications for the Clinch River Site for Tennessee Valley Authority).

Use of an ESP resolves significant issues and removes them from the plant licensing process itself. This can provide a major benefit by reducing risk to the investment which is made prior to and during the plant licensing process. However, it can extend the overall time involved in bringing a new plant into service if it takes place prior to submittal of the CP or COL application.

Limited work authorization

Regardless of the alternative path chosen, or whether an ESP approval is sought, a Limited Work Authorization (LWA) may be sought in accordance with 10 CFR Part 50.10 to permit certain construction activities to commence at a site prior to obtaining either a Part 50 CP following the two-step, or a Part 52 COL following the one-step, alternative.

Summary and future activities

Plant developers and prospective plant owners and operator/licensees currently have two alternative pathways available to enable new commercial power plants to be built and operated in the United States. The pathway used for all plants currently in operation provides for construction to be authorized based on a preliminary plant design and subsequently for operation to be authorized based on the final plant design, as constructed. The pathway used more recently for a few plants provides for an essentially complete standard plant design first to be certified for use and then to be referenced in applications for combined construction and operation approval at specific sites. Both pathways must separately also satisfy environmental impact reviews for the specific sites.

The first pathway allows investment in design development to be deferred until authorization to construct a plant at a specific site has been granted based on a preliminary design. It also allows for non-standard design details to be included, based on owner and operator/licensee preferences. Because the second pathway is based on use of a certified, standard plant design, the owner and operator/licensee uncertainties during construction and pending operation are significantly reduced, as compared to the first pathway. Also, the second pathway enables a plant vendor to invest in and obtain a design certification without having first to partner with a prospective plant owner. The certified design can then be marketed to multiple prospective owners.

There has not been sufficient experience with the second licensing pathway to determine which is preferable in most cases. Each pathway has advantages and disadvantages that can only be weighed in specific cases after the parties involved reach and implement detailed agreements.

Operating License (OL) Authorization for a license to operate a facility.

Introduction

Polymakers run the risk of "reinventing the wheel" when they make judgments on problems they face unless they are well informed about the context in which previous decisions of a similar nature were made, what alternatives were considered and why certain ones were chosen, and what personal and impersonal forces shaped a particular policy. ... The point is not to belabor the often misleading aphorism that "those who fail to study the past are condemned to repeat it," but rather to recognize that both continuity and change in history need to be understood to deal effectively with the present.

-Mazuzan and Walker, 1997

Advanced reactor designs, which may be cooled by water, gas, liquid-metal, and molten salt, often incorporate different fuels, materials, and fission product release barriers than found in current generation Light Water Reactors (LWRs) [defined in [US NRC \(2008\)](#) as LWRs licensed before 1997]. In recent years, some advanced reactor design developers assert that their selected fuel and coolant combinations offer increased safety margins, even in the absence of emergency power or operator intervention. In short, these developers contend their designs achieve safety by relying on inherent physical processes rather than engineered safety features. In addition to funding from the U.S. Department of Energy (DOE) to accelerate research and deployment of their technologies, advanced nuclear reactor proponents ([Martin, 2015](#); [Geist, 2015](#); [CRS, 2019](#)) advocate that successful deployment of non-LWR technologies requires significant changes in the current regulatory framework, which is burdensome and inflexible. Some are requesting a technology-neutral regulatory framework with provisions for a "test-then-license" approach, similar to the system used within the U.S. during the early years of nuclear. In 2017, the 115th U.S. Congress enacted two bills related to such concerns: the Nuclear Energy Innovation Capabilities Act of 2017 (NEICA), which required the DOE to develop a versatile fast neutron test reactor (VTR); and the Nuclear Energy Innovation and Modernization Act (NEIMA), which requires the U.S. Nuclear Regulatory Commission (NRC) to develop an optional regulatory framework suitable for advanced nuclear technologies. Both acts have been signed into law. The DOE currently plans to self-regulate the startup and oversight of the VTR ([INL, 2020](#)).

It is reasonable for applicants to request reductions in the time and costs required to gain regulatory approval for a design with significantly different characteristics than current-day LWRs. However, it is important to recognize the increased uncertainty associated with the performance of such reactor systems. As emphasized by the Advisory Committee on Reactor Safeguards (ACRS), "Decision makers should regard with caution quantitative claims of high safety performance for reactor systems still at the conceptual design stage" ([ACRS, 1989](#)). In this letter report, ACRS also emphasized issues that must be resolved, including the calculation and use of a source term for siting, the need for a containment building, and offsite emergency planning requirements. In a more recent letter, ACRS continues to emphasize the need for caution, noting that for non-LWRs, "Creative thinking will be required to identify such unique situations, to thoroughly identify the scenarios that will be the basis of the safety analysis and the source of releases, and to evaluate the suitability of sites" ([ACRS, 2019](#)).

In considering an alternative regulatory framework, important regulatory lessons can be gained by reviewing the startup and operating experience, as well as the regulation, of prior non-LWR examples. This chapter concentrates on two examples of commercial reactor prototypes built and operated in the U.S.—the Fort Saint Vrain (FSV) high temperature gas reactor (HTGR) and the Enrico Fermi Unit 1 (EF1) sodium fast reactor (SFR). This chapter also summarizes recent actions taken by the NRC to establish a new regulatory framework to address issues raised during these and other non-LWR licensing activities. Evaluation of the examples discussed in this chapter provides insights for avoiding difficulties with this new framework.

Background

The two non-LWRs focussed upon in this chapter were initially licensed by the U.S. Atomic Energy Commission (AEC), the predecessor for the NRC. At that time, the economic and political environment was significantly different than today. In his 1954 message to Congress advocating that the Atomic Energy Act (AEA) of 1946 be amended, President Eisenhower called for the AEC "to establish minimum safety and security regulation" that would encourage the use of nuclear technology for various commercial

Table 1 Power Reactor Demonstration Program (PRDP) rounds, applicants, and plants [based on information in Gillespie et al. (2016) and Allen (1977)].

	<i>Round I</i>	<i>Round II</i>	<i>Round III</i>	<i>Modified Round III</i>
Opened	January 1955	September 1955	January 1957	August 1962
Purpose or goal	Stimulate construction of prototype commercial reactors	Engage public utilities in construction of small, experimental reactors (< 40 MW)	Provide continuing assistance for development of power reactors; focused on large-scale commercial reactors	Support the construction of large baseload plants using proven technologies
Applicant: Plant Name (if available)	<i>Successful:</i> - Yankee Atomic Electric Company: Yankee Rowe - Nuclear Power Group: Dresden - Consumers' Public Power Group: Hallam - Power Reactor Development Corporation (PRDC): Enrico Fermi Unit 1	<i>Successful:</i> - City of Piqua, Ohio: Piqua - Rural Cooperative Power Association: Elk River - Dairyland Power Cooperative: LaCrosse <i>Unsuccessful:</i> - Chugach Electric Association - Wolverine Electric Cooperative - Holyoke Gas and Electric Company - Orlando Utilities Commission - University of Florida	<i>Successful:</i> - CVNPA: Carolinas-Virginia Tube Reactor - Consumer's Power Company: Big Rock Point - Northern States Power Company: Pathfinder - Philadelphia Electric Company (PECO)^a Peach Bottom Unit 1 (PB1) - Southern California Edison (SCE): San Onofre Unit 1 <i>Unsuccessful:</i> - East Central Nuclear Group/Florida-West Coast Nuclear Group	<i>Successful:</i> - Connecticut Yankee Atomic Power Company: Haddam Neck <i>Unsuccessful:</i> - City of Los Angeles Department of Water and Power: Corral Canyon
Approved and completed plants (Initial Criticality)	- Yankee Rowe PWR (1961) - Dresden BWR (1959) - Hallam Sodium Graphite Reactor (1962) - Fermi Fast Breeder Reactor (1963)	- Piqua (Organic Cooled/moderated reactor) - Elk River BWR (1962) - La Crosse BWR (1967)	- Carolinas-Virginia Tube Reactor Heavy Water Reactor (1963) - Big Rock Point BWR (1963) - Pathfinder BWR w/integrated nuclear superheat (N/A)^b - Peach Bottom HTGR (1967) - San Onofre PWR (1967)	Haddam Neck PWR (1968)

^aPECO was operator and major owner; however, PB1 was supported by a large consortium of more than 50 organizations.

^bAlthough Pathfinder was constructed, it never entered commercial operation due to complications associated with superheat production.

applications (Eisenhower, 1954). After the 1954 amendment to the AEA became law, the AEC initiated a three-round Power Reactor Demonstration Program (PRDP) [also referred to as the Cooperative PRDP, the Program for Demonstration Reactors, or the Power Demonstration Reactor Program] with incentives, such as funding for research and development and fuel at a reduced cost, to encourage deployment of a diverse collection of commercial nuclear power plant designs that were privately owned and operated. As summarized in Table 1, the PRDP resulted in 13 units being successfully completed, several of which were non-LWRs (Gillespie et al., 2016; Allen, 1977). Although this chapter focuses on issues encountered with deployment and operation of FSV and EF1, their experiences during licensing, startup, and operation are representative of what may occur with other first-of-a-kind (FOAK) demonstration reactors.

The two non-LWRs focussed upon in this chapter were licensed as Research and Development (R&D) facilities under Section 104(b) of the Code of Federal Regulations, Title 10—Energy, Part 50, Section 21 (10 CFR 50.21), “Class 104 Licenses; for Medical Therapy and Research and Development Facilities” (U.S. Government Publishing Office, 2020). After a plant had operated sufficiently to demonstrate its safety and commercial viability, the owner was expected to convert its Section 104(b) license to a Section 103 license (a commercial power plant license). As discussed by Bley and Malsch (2021) and Mazuzan and Walker (1997), this requirement was dropped in 1970, and the 104(b) process was eventually eliminated. Today, if data are insufficient to demonstrate the performance of reactor safety features, the applicant may pursue an NRC license using provisions of 10 CFR 50.43(e) for a prototype plant. Similar to the Section 104(b) approach, 10 CFR 50.43(e) provides a licensee more flexibility, but the NRC maintains the right to impose additional requirements on siting, safety features, or operational conditions for such plants. As noted by the NRC (see US NRC, 2007), insights from operation of a prototype may then be used in either the 10 CFR 50 or 10 CFR 52 processes described by Ray (2021).

In this chapter, insights gained from the FSV and EF1 experiences are highlighted in four areas: relevant operating experience; regulatory framework, review, and oversight; initial testing and operation; and complexity and technology advances. The importance of each area is first discussed.

Relevant operating experience

Domestic and international reactor operating experience provides important insights into component and system interactions and the importance of integrating requirements for design, construction, and operation. Relevant operating experience may be used by applicants to provide confidence that new aspects of their proposed design will accomplish required safety functions. Experience gained from the first commercial LWRs had limited application to non-LWRs. Operating experience from a prototype or test reactor, however, was used as a basis to request that the regulator reduce some of the required testing (see [Initial Testing and Operation](#)).

Regulatory framework, review, and oversight

Several references ([Moses, 2006](#); [Brey, 2014](#)) emphasize that it would have been advantageous if an established licensing framework (including regulatory guidance and design criteria) were in place prior to seeking regulatory approval. U.S. regulations and requirements evolved in response to emerging safety issues, such as the Browns Ferry fire ([Rempe, 2021](#)) and the Three Mile Island Unit 2 accident ([Skillman and Rempe, 2021](#)). Such experience is limited for non-LWRs. Without tools, such as a Standard Review Plan, Regulatory Guides, General Design Criteria, and regulator-endorsed standards, to evaluate the acceptability of a system or program, the regulator was forced to rely on analysis using tools with limited validation and on the limited relevant operating experience available. Although a regulator may allow more latitude in such cases, this latitude may be offset by the delays and additional resources needed to determine appropriate regulatory requirements.

An independent reviewer's perspective can be invaluable in efforts to avoid designing, building, and operating an unsuccessful plant. As part of their independent review of a new proposed reactor concept, the regulator should ask probing questions, such as the following ([Fuller, 1989](#); [Moses, 2006](#); [Moses and Lanning, 1985](#)):

- What parameters should be measured to demonstrate the plant can operate safely and how will these parameters be measured?
- Is this design consistent with regulatory requirements (as reflected in agreed upon design criteria, equipment qualification requirements, and technical specifications)?
- Are data and logic presented in the probabilistic risk analyses appropriate, especially information used to characterize the performance of safety and non-safety-related systems?
- Is there the potential for a system or component to cause unintended consequences that can adversely impact plant safety?

Although it may be expensive to address issues raised by an independent reviewer, it costs less than building and operating an unsuccessful plant. Experience indicates that proactive engagement with the regulator can reduce unnecessary delays and costs.

Initial testing and operation

Without relevant operating experience, the regulator will require extensive testing, including zero power, power ascension, and transient testing, to demonstrate the performance of the reactor and new systems incorporating FOAK equipment. Prior experience demonstrates that startup and operation of a non-LWR requires significant technical support and funding. In the FSV and EF1 examples, modifications were required to address issues identified during initial testing.

Complexity and technology advances

Experience indicates that it is wise to limit complexity and adoption of technological advances and if possible, to rely on proven systems and components. Although such advances are alluring, the FSV and EF1 experiences illustrate that plant unavailability overcomes any perceived benefits. Unnecessary problems associated with deployment and use of new component and system designs should be avoided by proactively identifying potential issues and by obtaining relevant test and operating data to address such issues. Operating and accident conditions, as well as maintenance activities, should be considered in the quest to identify potential issues with new components and systems. Again, an independent regulator may be beneficial in identifying potential issues.

Example 1—The Fort St. Vrain (FSV) high temperature gas reactor

Designed by General Atomics (GA), FSV was operated by Public Service of Colorado (PSC). After the AEC issued a permit, construction was initiated in September 1968 to build FSV near Platteville, CO.

Design

The FSV reactor, which operated between 1974 and 1989, was rated at 842 MW(t) with an electrical output of 330 MW(e). The reactor core used prismatic (hexagonal) graphite (H-451) blocks for fuel elements surrounded by a graphite moderator and reflector. The fuel contained high enriched uranium (originally, greater than 93 wt% U-235) and thorium carbide fuel particles with TRISO coatings (i.e., three coating layers: an inner layer of high-density pyrolytic carbon (PyC), a layer of silicon carbide, and an outer layer of high density PyC) (see Helmreich, 2021).

High-temperature helium was used as the primary coolant to produce steam at $\sim 538^{\circ}\text{C}$. Helium (at 4.8 MPa and $\sim 400^{\circ}\text{C}$) was discharged from four helium circulators and passed down through the core, where it was heated to a temperature of $\sim 775^{\circ}\text{C}$. The coolant then passed through 12 steam generator modules. The entire primary coolant system, including the active core, steam generators and helium circulators (shown on the left of Fig. 1), was contained within a pre-stressed concrete reactor vessel (PCRV). A filtered, vented confinement building enclosed the PCRV with essential piping and cabling. Table 2 summarizes FSV plant characteristics.

Fig. 1 Fort St. Vrain simplified flow diagram. Brey HL (2014) Initial start-up and testing of the Fort St. Vrain HTGR: Lessons learned which may be useful for the HTR-PM. In: *Proceedings of the HTR 2014 Conference*, Weihai, China, 27–31 October 2014, Paper HTR2014-71312. Available from <https://www.osti.gov/etdeweb/servlets/purl/20198167>.

Table 2 Fort St. Vrain design characteristics [based on information in Brey (2014) and Habush and Walker (1974)].

Parameter	Value
Thermal power	842 MWt
Net electric power	330 MWe
Power density	6.3 MW/m ³
Primary coolant	Helium
Pressure (inlet)	4.8 MPa
Temperature (inlet/outlet)	$\sim 400^{\circ}\text{C}/\sim 775^{\circ}\text{C}$
Steam temperature (main/reheat)	$538^{\circ}\text{C}/538^{\circ}\text{C}$
Fuel type	Hexagonal block
Fuel material	TRISO-coated high enriched uranium—thorium carbide
Primary system vessel	PCRVR with carbon steel liner
Total lifetime electric generation	~ 5500 GWh

After leaving the steam generator modules, steam entered the high-pressure (HP) turbine (see Fig. 1). After the HP turbine, the steam passed through a single stage turbine, which provided the driving force for the four helium circulators. This steam was then reheated to 538 °C in the upper (reheat) section of the 12 steam generator modules. The hot reheat steam was directed back to the intermediate-pressure (IP) turbine, then to the low-pressure (LP) turbine, and finally, to the condenser. Apart from the unique once-through steam generators, the secondary side of the plant was similar to a conventional fossil unit with 16.7 MPa main steam pressure, 538 °C main steam temperature, and 538 °C reheat steam temperature. The condensate system featured a full-flow demineralizer, three low pressure heaters, and a deaerator. Three boiler feedwater pumps directed the feedwater through two HP heaters and back to the steam generator modules.

With respect to deployment of a nuclear technology that could reap the economic and safety benefits associated with HTGRs, FSV operation led to several notable accomplishments:

- exceptionally good radiological cleanliness with low personnel exposures;
- outstanding safety features such as handling of temporary loss of forced cooling events without approaching core temperature limits;
- high cycle efficiencies (at that time, approaching highest in the power industry);
- generation of high-quality steam providing an excellent energy source for a multitude of process heat applications.

However, FSV experienced several operational issues associated with its FOAK systems and components (see [Initial Testing and Operation](#)).

Relevant operating experience

Although many features differed, FSV significantly benefitted from the design, construction, and operation of an earlier PRDP plant (see [Table 1](#)), the Peach Bottom Atomic Power Station Unit 1 (PB1). Using the PB1 experience, the design of FSV was modified to be a “proof-of-concept” demonstration that would provide the technical, regulatory, and operational bases for a larger commercial power plant design [Despite several potential plant owners using the FSV experience to prepare preliminary safety reports for 10 CFR 50 license applications (see [Ray, 2021](#)), all the FSV follow-on projects were canceled and GA withdrew the large HTGRs from the commercial market in 1975 (see [Moore et al., 1982](#))]. Significant aspects of the PB1 and other selected international HTGR experiences are highlighted here; more detailed information about HTGR demonstrations may be found in [Tsevekot \(2020a\)](#).

Operated by PECO, PB1 was a 40 MW(e) HTGR demonstration plant situated 80 miles southwest of Philadelphia on the Susquehanna River. The PB1 Nuclear Steam Supply System, which was designed by GA, included a helium-cooled, graphite moderated, 115 MW(t) reactor core operating at high temperature on a uranium-thorium fuel cycle. The reactor core consisted of 804 graphite fuel elements oriented vertically in a closely packed circular pattern within the reactor vessel. Each fuel element contained 30 annular fuel compacts comprised of fuel particles in a graphite matrix material. Similar to FSV, the fuel kernels in these particles were mixed uranium-thorium carbide. For the first PB1 core (Core 1), fuel particles were coated with a single layer of PyC to prevent hydrolysis; for the second core (Core 2), fuel particles had BISO coatings (an inner layer of low density PyC and an overlayer of high density PyC) to retain fission products and preclude hydrolysis. Core 1 was designed for continuous operation until its end-of-life (approximately 900 full-power days), but it only accumulated 452 effective full power days before Core 2 was installed. The premature installation of Core 2 was required because cracks had formed in the graphite sleeves surrounding the fuel compacts in around 90 of the fuel elements. The cracked sleeves were caused by swelling of the fuel compacts due to irradiation-induced dimensional changes in the fuel particle coatings ([Steward, 1978](#)).

PB1 went critical in March 1966 and shutdown in October 1974. FSV benefitted from several notable PB1 accomplishments:

- data for validating core physics methods;
- demonstration of reliable reactor control system operation;
- demonstration of steam generator operation and performance;
- demonstration of the performance of several unique gas reactor systems;
- demonstration that the plant could be operated in a load-following manner;
- demonstration of station availability (excluding planned shutdowns for R&D programs, the station availability over its lifetime was 88%).

FSV also benefitted from international licensing and operating experience regarding materials and fuel performance. For example, there was experience related to graphite cracking phenomena from the United Kingdom and related to TRISO fuel performance and dust generation and transport phenomena from Germany.

Regulatory framework, review, and oversight

Both the construction permit and operating license granted to FSV were issued under Section 104(b) of the Atomic Energy Act (AEA) of 1954, as amended. FSV was under construction when the AEA was amended in 1970 (see [Bley and Malsch, 2021](#)). Consistent with a Class 104(b) operating license, the NRC allowed a generous amount of latitude in regulating FSV. However, this latitude was offset by delays associated with determining appropriate regulatory requirements.

The ACRS review of the FSV construction permit was controversial. In fact, the ACRS did not reach a unanimous position in their letter report (ACRS, 1968). Member Hendrie dissented because FSV did not have a containment building; although Member Okrent approved FSV construction, he expressed concern about having a larger reactor, similar to the FSV design, without a containment at more populated sites unless additional features were added to mitigate major accidents.

Applicable regulatory guidance was limited, particularly in the areas of system design and plant safety attributes. There were often unnecessary delays when attempting to apply LWR regulatory requirements to the FSV design. Consequently, interactions between PSC and NRC on licensing issues often required significant negotiations and considerable (often third-party) analyses to obtain resolution. This was particularly evident with new regulations related to fire protection and environmental qualification of electrical equipment. Brey (2014) emphasizes that such negotiations resulted in added cost, delays in plant operation, diminished credit for the unique HTGR safety features of FSV, and lack of confidence between the regulator and the licensee. Because the burden of proof of compliance with the intent of the regulation lies with the plant owner/operator, Fuller (1989) observed that it is better to anticipate, rather than react to, regulatory changes. Hence, PSC established a licensing group with the explicit purpose of evaluating and actively participating in proposed rulemakings, thereby facilitating future implementation of regulatory requirements.

Several references (Moses, 2006; Fuller, 1989; Beck and Pincock, 2011) emphasize the importance of independent regulatory review and oversight. Reviews of the FSV licensing basis detected several incorrect or inadequately documented items:

- The design, which included steam generators and helium circulators located in large-sized PCRV penetrations, was developed assuming these penetrations had double closures. Hence, the accepted frequency (10^{-7} per year) for a pressure-induced failure of a large penetration on an LWR pressure vessel was assumed. However, the frequency for such LWR vessel penetration failures was estimated assuming the vessel is inspected to requirements specified within the American Society of Mechanical Engineers Boiler and Pressure Vessel Code. This wasn't the case for these large FSV PCRV penetrations.
- The design was developed assuming that the probability of turbine trip could be based on British Magnox reactor experience. However, the British Magnox reactors used multiple small turbine generators as opposed to the one large turbine generator used at FSV.
- The FSV FSAR included a base reactivity curve to estimate the large reactivity change observed following a major water ingress event in 1974. This base reactivity curve was not explained in any documentation nor in any other topical report, despite technical specifications recording it as a limiting condition for operation.

An independent regulator should ensure that the licensing basis is clearly understood and documented and that industry codes and standards are appropriately applied. Exceptions should be acknowledged, explained, and documented to avoid inaccurate safety evaluations or an unrecognized vulnerability.

Initial testing and operation

The initial startup and continued operation of FSV required significant instrumentation, technical support, and funding. Because of its unique design, special testing was initially performed to confirm design assumptions. Throughout its operation, additional testing was required to address unanticipated phenomena, resulting in a significant amount of lost electrical generation (Fuller, 1989; Brey, 2014; Habush and Walker, 1974). Training and licensing of plant operators also required special attention.

Initial testing

The initial testing program consisted of four independent phases. The first phase, Cold Check-Out testing, included validation of systems and associated instrumentation to assure conformance with design requirements. The second phase involved preliminary operating tests on systems and components as they were completed. Although it did not include the use of nuclear heat, it was a formal testing program to assure system and component operation was in accordance with design values. This phase of testing culminated with performance of a Hot Flow Test, which utilized the helium circulators to heat up the primary coolant system to operational temperatures. The latter two phases, which were part of the plant start-up testing program, were divided into two groups, the low power physics tests (Group A) starting at 2% power and the Rise-to-Power tests (Group B) cumulating at 100% power. The FSV testing program was the principle means for assuring plant nuclear safety using a License-by-Test basis with hold points at power levels of 2%, 5%, 30% and 70%.

Significant resources were required to complete this testing. For example, steam generator performance testing was performed at many steady state power levels. Within the steam generator, temperature and pressure measurements for the helium, feedwater, and steam were logged along with strain gauge readings. One of the 12 steam generator modules was highly instrumented with strain gauges and thermocouples in order to assess its performance throughout startup. Similar parameters were logged during and after nine transient conditions, which included trips and load shedding. The performance of an instrumented steam generator module with simulated plugging of one feedwater tube was evaluated. The steady state and transient performance of the turbine-generator was also tested. In addition, safety valve lifting and reseating pressures were tested.

During Rise-to-Power testing, FSV experienced several temporary loss of forced coolant events and reactor operational excursions (due to an unanticipated ingress of moisture into the primary coolant and movement of a portion of the reactor core). As the reactor approached 70% power, individual core region outlet temperatures fluctuated by as much as 40 °C, and power channel indications varied (one channel showed prompt power changes of up to 8% over 8–20 min cycles). After an extensive three-year testing and

analyses program, the cause of the fluctuations was determined to be thermal-induced movements of core components accompanied by periodic changes in bypass flows and crossflows of primary coolant helium. These fluctuations were eliminated by placing metal locking devices between the columns of fuel elements at the top of the core.

Training

Training of the FSV plant staff began in 1968 and was closely governed by AEC requirements (Brey, 2014; Habush and Walker, 1974). Because the reactor system had not previously undergone initial core physics and start-up testing, operators were required to secure a “Cold Senior License,” which involved more stringent requirements than licensing of operating personnel in a standard nth-of-a-kind nuclear power plant. The requirements set by the AEC on the FSV staff for achieving this license included training at a similar facility (PB1), training at FSV, and five eight-hour exams (three written and two oral) administered by AEC specialists.

Operating experience

The FSV operational history can be characterized by low availability and inconsistent power production. Several lessons were learned from this experience (Fuller, 1989; Brey, 2014).

FSV faced several challenges due to moisture ingress, not only from out-gassing of moisture from graphite as it was heated during plant startup but also from water-lubricated bearings in its FOAK helium circulators. Moisture ingress during shutdown conditions led to moisture being absorbed into graphite and insulation. One large water ingress event required the FSV helium purification system to remove large quantities of water, overwhelming the system’s capacity and leading to corrosion of helium circulating system components.

The FSV experience also provided important lessons regarding graphite performance. Changes in length, bowing, and cracking observed in graphite components were attributed to high fluence and temperature gradients.

The event that led to the premature FSV closure was severe cracking of the Incoloy-800 steam generator super-heater headers. Replacement of the headers was deemed too expensive to justify a plant restart. As observed by Moses (2006), one cannot assume that components will stay dry or not be exposed to corrosive chemicals used in the reactor system. Detailed metallurgy on all boundaries of the primary coolant system should be completed prior to installation and continuously evaluated during operation to avoid unnecessary extrapolation. Challenges to component integrity, such as fatigue, corrosion, and creep rupture, must be identified and addressed.

Complexity and technology advances

Although the FSV reactor design employed many of the fundamental principles that formed the basis for PB1, there were several significant differences: (1) PB1 had a 40-MWe power rating versus FSV had a 330-MWe power rating; (2) PB1 used a steel reactor vessel versus FSV had a PCRV; (3) PB1 used long, annular fuel elements with a solid graphite spine versus FSV used prismatic-block graphite fuel elements; and (4) PB1 used electric-motor-driven helium circulators with oil-lubricated bearings versus FSV used steam and water turbine-driven helium circulators with water-lubricated bearings. Ultimately, the added FSV design complexity led to its unavailability. In retrospect, several FSV references (e.g., Brey, 2014; Fuller, 1989) conclude it is prudent to limit complexity and adoption of technology advances associated with FOAK components and systems.

For example, consider difficulties associated with the helium circulator auxiliary system. Transients in this system were initiated by improper or inadequate response to control signals. Frequently, this resulted in relatively large quantities of circulator bearing water entering the primary coolant system. The subsequent cleanup of moisture from the primary coolant was a principle contributor towards low plant availability. In addition, failures in circulator bolts due to chloride stress corrosion cracking required a significant maintenance outage.

The FSV experience emphasizes the importance of using systems and components that are ruggedly simple in design and have a history of reliable operation and minimal maintenance. Where possible, safety-significant systems should be tested in a prototypic setup prior to installation. This is especially important for FOAK equipment for which there is limited availability of spare parts. This led Brey (2014) to recommend that advanced designers incorporate a generous over-build capability into systems and components. If there is extra margin in components, such as compressors, pumps, and motors, testing can be completed during operation with less chance for spurious trips.

Example 2—The Enrico Fermi Unit 1 (EF1) sodium cooled fast reactor

The world’s first commercial liquid-metal fast breeder reactor, which was developed as part of the AEC PRDP, was the Enrico Fermi Unit 1 (EF1) Nuclear Generating Station. In 1955, the Power Reactor Development Company (PRDC) was chartered to design, construct, and operate the reactor portion of EF1. The Detroit-Edison Company owned and operated the turbine-generator portion of the plant. Upon issuance of an AEC permit in 1956, construction was initiated to build EF1 near Monroe, Michigan (approximately 30 miles from Detroit, Michigan and 25 miles from Toledo, Ohio).

Design

The EF1 reactor was cooled by sodium and operated at essentially atmospheric pressure. Its first core (Core A) contained 26 wt% enriched metallic uranium fuel with zirconium cladding; with Core A, EF1 was designed to reach power levels of 200 MWt (67 MWe). The enriched uranium section of the core contained 105 driver fuel subassemblies (the term, subassembly, in a sodium-cooled reactor is analogous to the term, assembly, typically used in LWRs). The core was surrounded by 531 additional subassemblies containing depleted uranium. The core also contained two control rods and eight safety rods. With uranium and mixed plutonium-uranium oxide fuel (Core B and subsequent cores), EF1 was designed for operation at power levels of up to approximately 430 MWt (150 MWe).

The primary system was filled with sodium in December of 1960, and criticality was achieved in August 1963. The reactor was a loop design in which the liquid sodium primary coolant transferred its heat to secondary sodium in an external intermediate heat exchanger (see Fig. 2). The secondary sodium then passed through the tube side of three parallel steam generators and transferred heat to water on the shell side. The once-through steam generator design produced superheated steam, which turned the main turbine-generator. The core and primary loop were enclosed in a steel containment building, while the steam generators, turbine generator, and associated equipment were housed in a conventional building next to the containment. Table 3 summarizes EF1 plant characteristics.

With respect to deployment of a nuclear technology that could reap the economic and safety benefits associated with SFRs, there were several notable EF1 accomplishments:

- data for validating core physics methods;
- demonstration of performance and maintenance of sodium systems and components (including necessary design retrofits), such as large mechanical sodium pumps, the under-the-plug fuel handling system, sodium-heated steam generators, and intermediate heat exchangers;
- data for validating characteristics of thermal-hydraulic systems;
- demonstration of steam generator operation and performance;
- data to confirm predictions for subassembly radiation relaxation in high flux conditions.

However, EF1 also experienced several operational issues associated with its FOAK systems and components (see Initial Testing and Operation).

Relevant operating experience

SFR experience for EF1 was gained from several demonstrations: Experimental Breeder Reactor Unit 1 (EBR-I), Southwest Experimental Fast Oxide Reactor (SEFOR), and Experimental Breeder Reactor Unit 2 (EBR-II). In addition, the 6.5 MWe power generating Sodium Reactor Experiment provided experience with using sodium in a thermal nuclear reactor power system. Clearly, EF1 benefitted from prior and contributed to future SFR efforts.

Sited at what is now known as the Idaho National Laboratory (INL), EBR-I was designed to both breed plutonium and to produce electric power. On December 20, 1951, the 1.2 MWt reactor went critical and lit four 200-watt light bulbs, becoming the world's first fast reactor to generate electricity. EBR-I was fueled with weapon-grade (94 wt%-enriched) uranium. On June 4, 1953, the AEC announced that EBR-I had become the world's first reactor to demonstrate breeding of plutonium from uranium. Unfortunately, the reactor was designed with a prompt positive power coefficient of reactivity (fuel bowing led to increases in reactivity and power). On November 29, 1955, during an experiment to obtain information about this instability, the reactor had a partial (40–50%) core meltdown. The damaged core was removed, and the reactor was repaired and restarted in 1957 using a modified core design to preclude rod bowing. EBR-I continued to operate until it was shutdown in 1963.

SEFOR was an experimental fast breeder reactor located in Cove Creek Township near Strickler, Arkansas. Operating from 1969 to 1972, SEFOR was privately operated by General Electric and funded by the U.S. government through Southwest Atomic Energy Associates, a nonprofit consortium formed by 17 U.S. and European organizations. Using mixed plutonium-uranium oxide fuel, SEFOR generated 20 MWt of heat but no electricity. It was constructed to provide reactor physics data (including a demonstration of the Doppler response mechanism during initial operation) and to test inherent safety features of the oxide fuel/sodium cooling configuration. SEFOR provided thermal expansion data for characterizing the core response during accidents, confirming that such thermal expansion would stabilize the core. SEFOR was also used to obtain physics and engineering data at fuel compositions, temperatures, and states characteristic of power reactor operating conditions. In addition, SEFOR provided data for determining the Doppler coefficient of reactivity at temperatures up to fuel melting.

EBR-II was a 62.5 MWt (20 MWe), sodium-cooled, “pool-type” reactor, i.e., the heat exchangers for transferring heat to a secondary loop of liquid sodium were submerged in the reactor vessel. Also sited at what is now known as INL, EBR-II construction started in 1958. Criticality at low power without coolant was achieved on September 30, 1961; criticality with sodium coolant was achieved on November 11, 1963; and design power was achieved on September 25, 1969. EBR-II demonstrated the feasibility of a sodium-cooled fast breeder reactor operating as a power plant. Initially operating with metallic high enriched uranium fuel, EBR-II featured an adjoining facility that permitted continuous reprocessing and recycling. From 1964 until 1969, this facility processed spent fuel and fabricated fresh fuel.

Fig. 2 Enrico Fermi Unit 1 reactor. DTE Energy Company (2014) *Submittal of Revision 8 to the Fermi 1 Safety Analysis Report*. Letter from V. A. Kaminskis, Site Vice President, to U.S. Nuclear Regulatory Commission Document Control Desk, p. 17 of Enclosure 1.

Table 3 Fermi Unit 1 design characteristics [based on information in PRDC (1970, 1971) and US AEC (1974)].

Parameter	Value
Reactor power	~430 MWt (final design); 200 MWt (Core A ^a)
Net electric power	~150 MWe (final design); 67 MWe (Core A ^a)
Primary coolant (final design)	Sodium
Pressure (inlet/outlet)	0.83 MPa/0.14 MPa
Temperature (inlet/outlet)	316 °C/482 °C
Fuel type	Pin
Fuel	U-10% Mo (Core A ^a); UO ₂ and PuO ₂ -UO ₂ (Core B, etc. ^a)
Primary system configuration/housing	Loop/stainless steel reactor pressure vessel
Total lifetime electric generation	32 GWh (as of November 1972)

^aCore A was installed at startup (1963); proposed cores with oxide fuels were never installed.

Regulatory framework, review, and oversight

When the EF1 construction permit application was reviewed, no formal design or siting criteria and little preliminary design information were available. Relevant SFR operating experience was limited.

The January 1956 application for a construction permit to build the EF1 plant proved particularly contentious. In their review of the application, the ACRS concluded “there is insufficient information available at this time to give assurance that the PRDC reactor can be operated at this site without public hazard” (US NRC, 2002). The ACRS expressed concern that questions regarding the reactor’s safety could be resolved within PRDC’s proposed schedule for obtaining an operating license. The ACRS urged the AEC to expand fast breeder reactor experimental programs and obtain data to address issues raised during its review.

Public controversy that arose during congressional hearings regarding the EF1 application for a construction permit had far-reaching impact. In meetings with the chairman of the Joint Committee on Atomic Energy, AEC Commissioner Thomas Murray disclosed ACRS concerns about the EF1 application to support a request for additional R&D funds. The Joint Committee promptly requested the ACRS report, claiming the AEC had failed to keep them “fully and currently informed” as required by the 1954 Atomic Energy Act (US NRC, 2002; Okrent, 1981). Based on a more optimistic review by their staff, the AEC commissioners issued a construction permit by a vote of three to one (Murray was the lone dissenter). This and other on-going activities at the time formed the basis for 1957 legislative action to create a more open licensing process. The existing ACRS was made a statutory body with the responsibility to independently produce public reports on licensing cases. In addition, this incident led the Joint Committee to start questioning whether AEC regulatory responsibilities should be separated from developmental and operational functions (Mazuzan and Walker, 1997).

Approval for startup and operation of EF1 was also delayed because of several other factors: a sodium/water reaction incident due to steam generator testing (Stone et al., 1981); an unsuccessful lawsuit to halt the plant because of its siting in a populated area (Okrent, 1981); and as discussed in **Initial Testing and Operation**, a flow blockage incident that led to melting in two fuel assemblies. This latter incident was attributed to zirconium plates, which were added late in the design process and not shown on EF1 construction drawings. If an independent regulator had been involved, this event (see **Initial Testing and Operation**) might have been avoided because the design change would have been subjected to additional scrutiny and quality control requirements.

Initial testing and operation

EF1 first achieved criticality on August 23, 1963. During its first years of operation, an extensive testing program was conducted at low power levels to confirm reactor physics and thermal hydraulic method predictions. Power ascension testing above 1 MWt didn’t commence until December 29, 1965, when a license was received from the AEC to operate EF1 at power levels up to 200 MWt. Successful completion of the low-power testing program enabled operators to increase reactor power level to 10% (and later to 50%) for additional testing programs.

During a June 1966 test, operators observed that outlet temperatures for one fuel element were 20–25% higher than other fuel elements but values were dismissed as faulty thermocouple readings. During an August 1966 run at 50% power, operators observed that coolant outlet temperatures above two subassemblies were 40–47% above outlet temperatures from other subassemblies. During an October 1966 test, the operators observed several inconsistencies in plant instrumentation readings when the reactor power level reached 15% power. In addition to high outlet temperatures in several fuel elements, the control rods were more withdrawn than expected for this power level. At 15:09 on October 5, radiation monitors in the ventilation exhaust ducts from the reactor building alarmed and automatically shut dampers to isolate flow to the environment. Radiation monitors in four other plant areas were also indicating high values. The operators shut down the reactor, which was at 31 MWt, precluding any abnormal releases to the environment.

In September 1967, investigators lowered a periscope into the reactor and discovered an unknown metallic object had blocked sodium coolant from reaching the fuel. Later, the metal object was identified as a zirconium plate that had been installed in the reactor as a safety measure (as noted in **Regulatory framework, review, and oversight**, these zirconium plates were added late in the design process). During reactor operation, the plate became unfastened and obstructed sodium coolant flow to some fuel subassemblies. Investigations revealed damage had occurred in four fuel subassemblies, with significant melting in two subassemblies.

Damage to the reactor and fuel assemblies took approximately four years to repair. In May 1970, the reactor was ready to resume operation, and the reactor finally reached a power level of 200 MWt in October 1970. During 1971, EF1 only generated 19.4

gigawatt-hours (GWh) of electricity, corresponding to an average capacity factor of 3.4%. PRDC made the decision to decommission the plant in November 1972.

Complexity and technology advances

The EF1 differed from and was much more complex than first-generation LWRs. This added complexity was accepted because of potential economic benefits associated with breeder reactors; there was the potential to sell two products: the generated electricity and plutonium by-products. Hence, the increased complexity of EF1 was viewed as necessary to demonstrate the practical and economical use of the breeder reactor program.

During initial testing, several components, such as the check valves on the primary sodium pumps and the steam generators, were modified. As described by [Stone et al. \(1981\)](#), the steam generators, however, continued to be plagued with leaks at the tube-to-tubesheet weld joints. In addition, instrumentation indicated instability within the steam generators. Ultimately, all tube-to-tubesheet joints in the water header of all three steam generators were rewelded to make the units leak-tight; and flow restrictors were inserted into each water header tube to equalize the flow through the tubes and stabilize their performance.

In response to the 1966 flow blockage and fuel melting event, flow guards were added to the nozzles of all core and inner radial blanket subassemblies. In addition, PRDC incorporated improved neutron detectors with faster response times and an improved data acquisition and control system.

Recent actions to address non-LWR regulation issues

Over the past several decades, the NRC has engaged in several pre-application interactions with prospective applicants for non-LWR designs. These engagements included pre-application reviews of high-temperature gas cooled and sodium-cooled reactors. In 2010, the NRC staff identified several potential advanced reactor policy, licensing, and technical issues, such as: principal design criteria selection; licensing basis event selection; accident radiological source term development; containment functional performance criteria; emergency preparedness requirements; staffing requirements; safety-related systems, structures, and components selection; and physical security requirements (see [US NRC, 2010](#)). Since that time, the NRC staff has worked with stakeholders to address these issues and to establish NRC policy when enough information (i.e., clear industry proposals with supporting design detail, data, and analysis) is available to support decision-making. In more recent years, NRC advanced reactor activities are focussed on actions required by NEIMA ([CRS, 2019](#)) and to prepare for anticipated near-term non-LWR submittals. NEIMA Section 103 requires that the NRC “complete a rulemaking to establish a technology-inclusive, regulatory framework for optional use by commercial advanced nuclear reactor applicants for new reactor license applications.” [Bley and Malsch \(2021\)](#) and [Fleming \(2021\)](#) discuss recent actions by the NRC staff and industry to address non-LWR issues. As these actions are implemented, it is important to consider difficulties encountered during prior non-LWR licensing, startup, and operating activities.

Summary

This chapter reviews two examples of FOAK non-LWRs that were authorized by the predecessor of the NRC, the AEC, as R&D facilities under Section 104(b) under the provisions of 10 CFR 50. In deploying and operating a non-LWR under this more flexible Section 104(b) process, the FSV and EF1 examples provide several important lessons in four areas:

- relevant operating experience
- regulatory framework, review, and oversight
- initial testing and operation
- complexity and technology advances

This chapter also summarizes recent actions taken by the NRC and industry to address issues identified during these and other non-LWR licensing activities. These actions support NRC activities to establish a new regulatory framework for optional use in future commercial advanced nuclear reactor license applications. Careful evaluations of issues encountered during licensing, as well as during startup and operation of FOAK reactors, offer insights that may be used to improve this new framework.

Acknowledgments

The author wishes to acknowledge the reviews provided by Dr. Michael L. Corradini, Professor Emeritus in Nuclear Engineering and Engineering Physics, University of Wisconsin; Mr. Harold B. Ray, Public Utility Executive Vice President, Chief Nuclear Officer (Retired); and Dr. Neil Todreas, Professor Emeritus in Nuclear Engineering, Massachusetts Institute of Technology. These individuals have unique knowledge regarding information discussed in this chapter and their expertise is greatly appreciated.

Glossary

Nuclear Licensing The activities undertaken by a Regulatory Body in order to grant a license to permit the construction, commissioning, operation, and decommissioning of a nuclear installation.

Nuclear Regulation The inspection, assessment, permissioning and enforcement activities necessary to control the siting, design, construction, commissioning, operation and decommissioning of nuclear installations.

Nuclear Safety All the activities that are required to be undertaken to protect workers, the public, and the environment from the effects of ionizing radiation as a consequence of operating nuclear facilities during both normal and accident conditions.

Nuclear Security All the activities that are required to be undertaken to prevent the theft of and illegal transfer of nuclear or radioactive materials and to prevent unauthorized access to or sabotage of nuclear facilities.

Nuclear Site License A legal document to permit specified activities on a designated nuclear site.

Radioactive Waste Radioactive materials that are of no further use and destined for interim storage and eventual disposal.

Regulatory Body The body within a State with the legal authority to conduct the regulation of nuclear installations including the inspection, assessment, permissioning and enforcement activities necessary to control the siting, design, construction, commissioning, operation and decommissioning of nuclear installations.

Spent Fuel Nuclear fuel that has been removed from a reactor when it has come to the end of its useful life and is no longer required for power generation.

Introduction

It is clear that the international community regards the regulation of nuclear safety (and nuclear security) to be a national responsibility (IAEA, 1994, 1997, 1980, 2016a). Nuclear safety regulation and nuclear security regulation are in essence nuclear law enforcement; and because there is no universal legal system that has jurisdiction in all countries, there can be no single nuclear safety or nuclear security regulatory system or regulatory body. However, the radioactive fallout from a nuclear accident can have international consequences; and hence, the international community via the International Atomic Energy Agency (IAEA), the OECD/Nuclear Energy Agency (NEA) and other international organizations have developed international requirements and guidance to help countries with, or aspiring to have, nuclear power programs to develop a consistent approach to nuclear safety and security regulation and nuclear facility licensing.

This article provides an insight into the international legal framework for nuclear safety regulation and the licensing of nuclear installations. It also provides an overview of the regulatory approaches taken in a number of countries with significant nuclear power programs. The regulatory approach in the United States is excluded from this article because it is described in Bley and Malsch (2021a,b) and Ray (2021). In addition, more detailed information on nuclear safety regulation can be found in Rempe and Williams (2021).

Nuclear Law

Through the IAEA, the international community has developed a legally based international nuclear law architecture to not only promote the importance of nuclear safety and its regulation, but also to assist states in the development of robust legal systems to adequately control the peaceful use of nuclear energy. Nuclear law can be regarded as “the body of special legal norms created to regulate the conduct of legal or natural persons engaged in activities related to fissionable materials, ionizing radiation and exposure to natural sources of radiation” (IAEA, 2003). The objective of nuclear law is to provide a legal framework for conducting activities related to nuclear energy and ionizing radiation in a manner that adequately protects individuals, property, and the environment.

The IAEA identify a number of fundamental principles that can be used to distinguish nuclear law from other aspects of national law. The 11 principles of nuclear law are:

- The safety principle;
- The security principle;
- The responsibility principle;
- The permission principle;
- The continuous control principle;
- The compensation principle;
- The sustainable development principle;
- The compliance principle;
- The independence principle;
- The transparency principle; and
- The international co-operation principle.

While all these principles are important, those that are key to the delivery of effective nuclear safety regulation and licensing are outlined below.

The Safety Principle

The safety principle reflects the fact that safety is paramount and unless the use of nuclear energy is safe its use should be prevented. Therefore, given the special nature of the risks that arise from the use of nuclear energy, the primary objective of nuclear law is to promote the exercise of caution and foresight to prevent damage. In addition, the fundamental purpose of any regulatory regime is to balance the social risks and benefits. It is therefore important that the risks associated with nuclear energy are well understood. It is accepted that the stringency of legal arrangements should be related to the potential for harm, i.e., a graded approach.

The Security Principle

The security principle reflects the potential for harm to society that could arise from the theft or diversion of nuclear materials or technologies. For these reasons special legal measures are required to protect nuclear materials and installations. This principle relates to both physical security and safeguards issues.

The Responsibility Principle

This principle primarily reflects the need for someone to be responsible for ensuring safety. In the case of nuclear law this responsibility falls on the licensee that has been granted authority to carry out nuclear related activities. The licensee also has the responsibility to carry the burden of financial liability for any damage that may be caused by its activities. In the context of the "responsibility principle," the licensee is responsible for safety, those aspects of security that are within its control, and the protection of the environment.

The Permission Principle

Where an activity has the potential to cause harm to people or the environment, it is appropriate for the law to require that permission to carry out such an activity is obtained by the licensee before the activity is undertaken. Given the special risks associated with the use of nuclear energy, nuclear law normally requires permission to be obtained before activities involving fissionable material are undertaken. Permission can be in a variety of forms: such as a license, an authorization, a permit, an approval, a consent, etc.

Continuous Control Principle

This principle reflects the fact that a permission to do something is not a one-off activity. The person giving the permission, normally the Regulatory Body, will need to be convinced that the licensee's activities are being continuously conducted in a safe and secure manner. It is through this principle that the nuclear law requires that the Regulatory Body is given the right of access to nuclear facilities in order to effectively monitor the licensee's activities.

The Independence Principle

Nuclear law places particular emphasis on the fact that regulatory decisions relating to nuclear safety are not subject to undue influence or interference from those entities that have a responsibility for the promotion and use of nuclear energy. The Regulatory Body must therefore be independent of the nuclear industry and parts of government that have a role in the promotion of the nuclear industry.

The Transparency Principle

In some countries, the nuclear industry grew out of military programs; and hence, the users of nuclear energy have therefore often been seen as secretive. The transparency principle requires that those who are involved in the regulation, development or use of nuclear materials should make available information on how nuclear materials are being used and on accidents that have occurred that could have an impact on human health or the environment.

Nuclear Related Conventions

The IAEA has developed a number of international conventions in the area of nuclear safety and nuclear security in order to provide the international community with the necessary confidence that nuclear safety and nuclear security is being delivered to consistent standards. The key Conventions are: the Nuclear Safety Convention (IAEA, 1994), the Joint Convention on the Safety of Spent Fuel Management and on the Safety of Radioactive Waste Management (IAEA, 1997), and the Convention on the Physical Protection of Nuclear Materials (IAEA, 1980, 2011, 2016a).

Nuclear Safety Convention

The Convention on Nuclear Safety was adopted in Vienna on 17 June 1994 and came into force in the autumn of 1996. The Convention was introduced following the 1986 accident at Chernobyl (Sich, 2021) with an aim to raise nuclear safety standards worldwide.

The Convention aims: to achieve and maintain a high level of nuclear safety worldwide through national measures and international cooperation; to establish and maintain effective defenses in nuclear installations in order to protect individuals, society and the environment from the harmful effects of ionizing radiation; and to prevent accidents [*Safety Principle*]. The Convention applies to the safety of nuclear installations.

Contracting Parties to the Convention are required to implement the obligations set out in the Convention through their legal and regulatory frameworks. This framework should provide for: the establishment of national safety requirements and regulations; a licensing system for nuclear installations [*Permission Principle*]; the prohibition of the operation of a nuclear installation without a license; a system of regulatory inspection and assessment of nuclear installations [*Continuous Control Principle*]; and the enforcement of regulations and license conditions.

The Contracting Party is also required to establish a Regulatory Body to implement its national legislative and regulatory framework. The Contracting Party is required to ensure that the Regulatory Body is provided with adequate authority, competence, and financial and human resources, in order to fulfill its responsibilities. The Contracting Party is also required to ensure that there is an effective separation between the Regulatory Body and any other organization that is concerned with the use or promotion of nuclear energy [*Independence Principle*].

The Convention requires the Contracting Party to ensure that the responsibility for nuclear safety rests with the holder of the relevant license [*Responsibility Principle*] and that all organizations engaged in activities directly related to nuclear installations give due priority to safety.

The requirements of the Convention are based to a large extent on the principles contained in the IAEA Safety Fundamentals document "The Safety of Nuclear Installations" (IAEA, 1993).

Joint Convention on the Safety of Spent Fuel and the Safety of Radioactive Waste Management

The Joint Convention on the Safety of Spent Fuel Management and on the Safety of Radioactive Waste Management (IAEA, 1997) was adopted on 5 September 1997, and it entered into force on 18 June 2001. The key aims of the Joint Convention are: to achieve and maintain a high level of safety worldwide in spent fuel and radioactive waste management; to ensure that during all stages of spent fuel and radioactive waste management there are effective defenses against potential hazards so that individuals, society and the environment are protected from harmful effects of ionizing radiation, now and in the future, in such a way that the needs and aspirations of the present generation are met without compromising the ability of future generations to meet their needs and aspirations; and to prevent accidents with radiological consequences.

Contracting Parties to the Joint Convention are required to implement the obligations set out in the Convention through a legal and regulatory framework. The framework should provide for: national safety requirements and regulations for radiation safety; a system of licensing of spent fuel or radioactive waste management activities; the prohibition of the operation of spent fuel or radioactive waste facilities that do not have a license; appropriate institutional control; regulatory inspection; enforcement powers and allocation of responsibilities. The regulatory framework is expected to ensure that at all stages, both spent nuclear fuel and radioactive waste is managed in such a way that individuals, society and the environment are adequately protected against radiological hazards.

A Contracting Party is required to establish a Regulatory Body to implement its national legislative and regulatory framework. The Contracting Party is required to ensure that the Regulatory Body is provided with adequate authority, competence, and financial and human resources, in order to fulfill its responsibilities. The Contracting party is also required to ensure that there is an effective independence of the Regulatory Body in relation to any other organizations that are involved in both spent fuel and radioactive waste management. The national Regulatory Body is required to have powers to license spent fuel and radioactive waste management facilities to enable the control of the siting, design, safety assessment, construction, commissioning, operation and decommissioning of such facilities. In relation to radioactive waste or spent fuel disposal facilities, the Convention requires a Contracting Party to preserve records of the location, design and radioactive inventories of such facilities.

Convention on the Physical Protection of Nuclear Materials and Facilities

The Convention on the Physical Protection of Nuclear Materials was adopted in 1980 and came into force in 1987. However, it was limited to the physical protection of nuclear materials during international transport. It did not cover the protection of nuclear facilities or nuclear materials in domestic use, storage or transport. In 2005 an amendment to the Convention (IAEA, 2005a,b) was adopted to make it legally binding on States to establish, implement and maintain an appropriate physical protection regime for nuclear materials and nuclear facilities under their jurisdiction. This amendment came into force in 2016 (IAEA 2016a).

Guidance (IAEA, 2011) on how to implement the revised Convention outlines 12 fundamental principles relating to the security of nuclear materials and nuclear facilities. It is the responsibility of the State to establish, implement and maintain a physical protection regime. This regime should include establishing and maintaining a legislative framework to govern physical protection;

establishing a Competent Authority which in effect is similar to the nuclear safety Regulatory Body, ensuring that the prime responsibility for implementing physical protection of nuclear material and nuclear facilities rests with the licensee; and ensuring that priority is given to the establishment of an effective security culture. However, the responsibility for nuclear security is placed on the Government of the Member State.

IAEA Requirements and Guidance

To support the nuclear safety Conventions, the IAEA has produced extensive guidance on nuclear law (IAEA, 2003) and established a comprehensive set of nuclear safety standards and guides [see the IAEA website (www.iaea.org) for further information]. The IAEA Safety Standards have three main tiers: Fundamentals; Requirements; and Guides. The Fundamental Safety Principles (IAEA, 2006) provide the high-level aims that Member States using or aspiring to use nuclear energy should comply with. These principles define the roles and responsibilities of the licensee, the regulator, and the government. In the second tier there are General Safety Requirements (GSRs) (7 parts) and Specific Safety Requirements (SSRs) (6 parts) such as SSR 2 that addresses the safety of nuclear power plants (NPPs). In relation to regulation and licensing GSR 1—Governmental, Legal and Regulatory Framework for Safety (IAEA, 2010) is the key document.

The consistent theme of the international nuclear safety and nuclear security framework is the protection of people and the environment from the harmful effects of ionizing radiation. As a result, most Regulatory Bodies indicate that their primary mission or safety objective is the protection of people and the environment. The Regulatory Bodies also provide assurance to their Government that nuclear energy is being used safely and securely and in accordance with the legal requirements.

European Union—Nuclear Safety Directives

Nuclear safety

The European Union has competence in relation to nuclear safety; and hence, EU Member States are subject to The Nuclear Safety Directive (EU, 2009, 2014). The objectives of the Nuclear Safety Directive (EU, 2009) are to establish a European Community wide framework to maintain and promote continuous improvement of nuclear safety and its regulation; and to ensure that EU Member States have appropriate national arrangements to provide a high level of nuclear safety to protect workers and the public from the dangers arising from ionizing radiations from nuclear installations. The Directive places a number of obligations on EU Member States including the requirement to establish and maintain a national legislative and organizational framework for nuclear safety at nuclear installations. This “national framework” is required to establish responsibilities for the adoption of national nuclear safety requirements; and the provision of a licensing regime, a system of nuclear safety supervision, and enforcement actions.

The Directive in many ways mirrors the IAEA Nuclear Safety Convention in that it requires EU Member States to establish and maintain a competent regulatory authority, ensure that the regulatory authority is functionally separate from bodies associated with the promotion or use of nuclear energy and that the responsibility for nuclear safety rests with the licensee of the nuclear installation.

In 2014, the Nuclear Safety Directive was amended (EU, 2014). This amending Directive provided more substantive technical rules in the field of nuclear safety including safety culture. It also added more detail on the obligations of EU Member States including additional specific obligations relating to an EU Member State’s national nuclear safety framework. These new obligations provided more focus on the nuclear safety objectives for nuclear installations, how the new obligations should be achieved, requirements for more detailed assessment of nuclear installations including periodic safety review, and on-site emergency preparedness. In addition to the peer reviews required by the initial Nuclear Safety Directive (EU, 2009), the amending Directive requires EU Member States to conduct topical peer reviews every 6 years on a safety issue that is selected jointly by the EU Member States, the intention being to provide a mechanism for shared learning. Although the new Directive, is more detailed than its predecessor, it again mirrors the intent of the IAEA Nuclear Safety Convention.

The amending Directive was adopted on the 8 July 2014 and entered into force on 14 August 2014. Member States were required to transpose the Directive into their National laws by 14 August 2017 and report to the European Commission on its implementation by July 2020.

Safe management of spent fuel and radioactive waste

In 2011 the EU introduced a Directive on the safe management of spent fuel and radioactive waste (EU, 2011). This Directive establishes a Community framework for ensuring responsible and safe management of spent fuel and radioactive waste. It ensures that EU Member States provide for appropriate national arrangements for a high level of safety in spent fuel and radioactive waste management. The scope of the Directive is similar to that of the IAEA Joint Convention on the Safety of Spent Fuel Management and the Safety of Radioactive Waste Management.

The Directive requires EU Member states to establish a national framework for spent fuel and radioactive waste management that includes a system of licensing of spent fuel and radioactive waste facilities and activities; appropriate regulatory controls and enforcement actions. EU Member States are required to establish a competent regulatory authority and to ensure that this authority has the necessary legal powers and human and financial resources to fulfill its obligations; and that the regulatory authority is independent of organizations concerned with the promotion or utilization of nuclear energy or with the management of spent fuel and radioactive waste. Like the IAEA Joint Convention (IAEA, 1997), the Directive requires that the prime responsibility for the safety of

spent fuel and radioactive waste management rests with the license holder. EU Member States are required to make and implement national policies for the responsible and safe management of spent fuel and radioactive waste. EU Member States are also required to have a national program with clear milestones to show spent fuel and radioactive waste will be managed over time, including concepts for the post closure period of a disposal facility.

Similar to the IAEA Joint Convention, EU Member States are required to produce national reports every 3 years. The Directive requires EU Member States to submit the national report to the European Commission.

Case Studies

The following case studies are used to illustrate how international requirements are implemented at a national level. These case studies focus on countries, other than the United States, that have substantial nuclear power programs. The case studies are structured to give an insight into each country's legal framework, regulatory body, regulatory approach, and licensing, inspection and enforcement methods.

Case Study 1: Nuclear Regulation in the United Kingdom

The United Kingdom's (UK) civil nuclear power program grew out of the UK's post-war military imperative of producing plutonium for nuclear weapons. The UK built two plutonium-producing reactors, the Windscale Piles, between 1947 and 1950. In 1953 the UK commenced the construction of the first of eight gas-cooled reactors that had been designed to produce both plutonium and electricity for the national grid. HM Queen Elizabeth opened the first of these reactors, located at Calder Hall in October 1956. The 1955 White Paper entitled "*A programme of nuclear power*" identified nuclear power as a strategically diverse source of electricity (UK, 1956), and the UK embarked on a nuclear power program that resulted in the construction and operation of 41 nuclear power reactors. The UK also developed the full fuel cycle capability including uranium enrichment, nuclear fuel manufacture, spent fuel reprocessing, and radioactive waste treatment and storage facilities. In addition to this civil nuclear power program, the UK carried out a major nuclear research program with Europe's first atomic pile opening in 1946. Five major nuclear research sites housed a variety of research reactors, including fast breeder reactors and experimental fuel cycle facilities. In the early years of nuclear development, the UK's nuclear activities were not subject to statutory regulation.

Legal framework

The UK's nuclear safety legislation has developed over the years (Salter, 2010; Tromans, 2010). Following the accident in 1957 at one of the Windscale Piles and with the expansion of the civil nuclear power program, the UK introduced its first "Licensing and Insurance" Act, the Nuclear Installations Act of 1959. This Act was subsequently amended in 1965 to take on board new international treaties relating to nuclear liability and insurance. The 1965 Nuclear Installations (as amended) Act (UK, 1965) was a licensing and insurance Act.

The Nuclear Installations (as amended) Act 1965

The key feature relating to nuclear safety and licensing of the 1965 Act was to provide regulatory control over the construction and operation of NPPs and the associated radioactive waste. The Act states that no person may use a site for the purpose of installing or operating a nuclear reactor or any other installation that has been prescribed in law, unless a nuclear site license has been granted. The power to grant licenses was initially given to Ministers but subsequent amendments transferred this power to the independent Regulatory Body, currently this is the Office for Nuclear Regulation (ONR). The 1965 NI Act also enables the government to prohibit certain operations except under permit. Under the Act a nuclear site license can only be granted to a corporate body and once granted, it is not transferable. A nuclear licensed site cannot be de-licensed and hence be removed from ONR's regulatory control, unless the licensee can demonstrate that there is "no danger" from ionizing radiations from anything on the site. ONR has the power to vary a nuclear site license and to attach conditions at any time that are necessary or desirable in the interests of safety with respect to the design, siting, construction, installation, operation and maintenance of any plant installed on the site. ONR also has the power under the 1965 Act to attach conditions to a nuclear site license in relation to the handling, treatment and disposal of nuclear matter, which includes radioactive waste.

ONR has the power to revoke a nuclear site license at any time. A nuclear site licensee may at any time surrender the license to ONR. However, even if the nuclear site license is revoked by ONR, or the licensee surrenders the license, the licensee retains responsibility for a "period of his responsibility." At any time during this period ONR has the power to give the licensee directions in order to prevent risk of injury to any person or damage to any property from ionizing radiations from anything remaining on the site. Hence, the licensee remains responsible for the site until ONR has granted a new license for the site to a new licensee, or the licensee can demonstrate that there is no danger from ionizing radiation from anything on the site.

Health and Safety at Work etc. Act 1974

The primary legislation governing Health and Safety in the workplace in the UK is the Health and Safety at Work Act etc. 1974 (HSWA) (UK, 1974). The HSWA introduced the concept of goal setting and proactive approaches to safety management. The objectives of the 1974 Act are: to secure the health, safety and welfare of persons at work; to protect others against risks to health and

safety arising from work activities; and to control dangerous substances and preventing the unlawful acquisition, possession and use of such substances. The common law principle of a “Duty of Care,” is enshrined in law with the HSWA. In the HSWA specific roles, responsibilities and duties are placed on the employer, the employee (this is applied very broadly—and may include some contractors and agency staff) and others (e.g., the emergency services and local authorities). It defines the enforcement powers and arrangements for prosecution, and the applicability of the legislation to the crown.

Under Section 2 of the HSWA, the employer is required to ensure, so far as is reasonably practicable, the health, safety and welfare at work of all his employees. Section 3 requires employers and the self-employed to ensure so far as is reasonably practicable the safety of persons other than employees, for example contractors, visitors and the general public. A key phrase in the Act is “so far as is reasonably practicable,” often abbreviated to SFAIRP. SFAIRP involves comparing the risk reduction achieved by a safety measure (or range of measures) with their cost (money, time, trouble). The measure(s) should be implemented unless the cost is grossly disproportionate to the risk averted. The burden of proof as to what is reasonably practicable rests with the employer.

The Ionizing Radiations Regulations 2017

The Ionizing Radiations Regulations (IRR17) (UK, 2017) implements the worker safety aspects of the Basic Safety Standards Directive (96/29/2013/59/Euratom). IRR17 covers radiation protection requirements in the UK. The regulating authority is the Health and Safety Executive (HSE). IRR17 identifies requirements to obtain authorization from and provide notification to HSE; to perform prior risk assessment; to provide and maintain personal protective equipment and engineering controls and to adhere to the dose limits specified in the regulations. These regulations also discuss arrangements for the management of radiation protection, for the designation of areas and classification of personnel, and for the control of radioactive substances. ONR Inspectors enforce these regulations on nuclear licensed sites and on defense nuclear sites that are not licensed under the NI Act.

The Radiation (Emergency Preparedness and Public Information) Regulations 2019

The Radiation (Emergency Preparedness and Public Information) Regulations UK (2019) implements the Euratom Basic Safety Standards Directive (2013/59/Euratom). The regulations establish a framework of emergency preparedness measures to ensure that members of the public are properly informed and prepared, in advance, about what to do in the unlikely event of a radiation emergency occurring and given information if a radiation emergency actually occurs.

The regulations require operators to identify all hazards that have the potential to cause a radiation emergency, and then evaluate the range of possible on and offsite consequences for a reflective range of all hazards identified. The key outcome is a consequence report to the local authority, with a recommended technical distance for the detailed emergency planning zone. The local authority uses this output to develop and implement the off-site emergency response plan that is specific to the nuclear site.

The regulations allow for a graded approach to planning for a site that is appropriate, proportionate and flexible to the risks identified in the hazard evaluation process. The regulations also require a review of hazard evaluation at least every 3 years and for a review to be undertaken where there is a material change to the work with ionizing radiation on the site. Emergency plans are required to be tested at least every 3 years. For nuclear licensed sites ONR is responsible for oversight of the regulations.

Energy Act 2013—Part 3 Nuclear Regulation

The Energy Act 2013 Part 3 (UK, 2013) sets up the Office for Nuclear Regulation (ONR). ONR is the UK’s nuclear safety Regulatory Body and the nuclear security Competent Authority. The Act defines the principle function of ONR, gives it the power to enforce relevant statutory provisions of the Nuclear Installations Act relating to licensing, reporting of and inquiries into dangerous occurrences, the appointment of inspectors, the provision of powers to inspectors, and recovery of expenses. The Act enables the Secretary of State to make regulations for the purposes of nuclear safety, nuclear site health and safety, and nuclear security, safeguards and transport of nuclear and radioactive materials. The Secretary of State has the power to ensure that sensitive nuclear information relating to activities carried out on or in relation to civil nuclear premises is protected in the interests of national security.

Regulator—Office for Nuclear Regulation (ONR)

The Office for Nuclear Regulation (ONR) is responsible for the regulation of nuclear safety and security across the UK (see www.onr.org.uk). ONR is a statutory corporation that is independent of the nuclear industry and independent of those parts of the UK Government that are responsible for the promotion of nuclear energy and the management of radioactive waste. ONR’s sponsoring department in the UK Government is the Department for Work and Pensions. ONR has a Board of Directors that has corporate responsibility for ensuring that ONR fulfills the aims set out in the “Framework Document between the Department for Work and Pensions and the Office for Nuclear Regulation” (ONR, 2018). ONR’s mission is to provide efficient and effective regulation of the UK’s nuclear industry, holding it to account on behalf of the public. ONR has five regulatory divisions: Operating Facilities; New Reactors; Sellafield Decommissioning, Fuel and Waste; Civil Nuclear Security and Safeguards; and Technical. ONR’s resources are set out in its 2016–20 Strategy (ONR, 2016a); at the end of 2020, ONR expects to have around 500 specialist staff in post and have a budget of £85.4 m. Of this £85.4 m, some £84 m is recovered from charging the nuclear industry and £1.4 m is a government grant.

Regulatory approach

The UK’s civil nuclear program is diverse, covering not only nuclear research facilities and activities, but also activities and facilities associated with the whole nuclear fuel cycle including the storage and disposal of radioactive waste. Hence, as the regulatory

framework developed, it became difficult to apply a prescriptive approach to regulation. In a prescriptive regime, the Regulatory Body prescribes the rules or regulations that the licensee must comply with. The range of types of facilities and technologies made it impossible for the Regulatory Body to develop a comprehensive set of safety requirements and associated regulations for all the facilities and activities. The UK therefore developed a “goal-setting” approach to the regulation of its nuclear facilities. In this approach, the legal framework sets the “nuclear safety goals” and it is the responsibility of the licensee to demonstrate compliance with the goals. This approach enabled the licensees to be flexible in determining how to meet the nuclear safety goals and hence tailor their nuclear safety arrangements to fit the nuclear activity and its associated hazards. Because this approach requires the establishment of specific safety goals and targets, it is necessary for the Regulatory Body to have highly professional and competent staff not only to develop meaningful safety goals and targets, but also to effectively evaluate the Licensee’s nuclear safety arguments.

Licensing and enforcement

ONR’s approach to licensing is set out in “Office for Nuclear Regulation—a Guide to Nuclear Regulation in the UK” (ONR, 2016b) and “The Licensing of Nuclear Installations” (ONR, 2019b). ONR regulates 37 licensed nuclear sites associated with operating nuclear power stations, NPPs under construction, fuel cycle facilities, waste management facilities and some defense-related activities. To obtain a nuclear site license for a new site to construct and operate an NPP or any other prescribed facility, the applicant is required to demonstrate to ONR that it is a fit and proper corporate body. In essence, it has to demonstrate that it is not only the “controlling mind” but also an “intelligent customer” for the services it will procure. It also has to show that it has sufficient financial resources to undertake the intended activities and liabilities. The applicant is also required to produce a “management prospectus” that outlines its organization, quality management arrangements and its arrangements for compliance with the conditions attached to the nuclear site license (ONR, 2017). In the case of an NPP, the license applicant is also required to produce a “Pre-Construction Safety Report” (PCSR) for the NPP to be built on the site.

ONR will judge the adequacy of the license applicant’s documentation against its Safety Assessment Principles (ONR, 2014); when it is satisfied with the documentation, ONR will grant the applicant a nuclear site license. The Government introduced an optional process for the certification of new nuclear reactor designs. This Generic Design Assessment (GDA) (ONR, 2019a; EA, 2019) process is a contractual arrangement between a reactor vendor and two regulators—ONR and the Environment Agency for England and Natural Resources Wales. At the end of the process, if the regulators are satisfied with the adequacy of the design, the environment regulator will issue a Statement of Design Acceptability (SODA) and ONR will issue a Design Acceptance Certificate (DAC). These documents are given to the reactor vendor; should a license applicant propose to construct an NPP design with a DAC and SODA, the license applicant is still required to produce a site specific PCSR. In assessing the PCSR, the regulators will take account of the work done during the GDA process.

Once permission to commence construction on the nuclear licensed site has commenced, the licensee requires permissions from ONR and where appropriate, the environment agencies to commence inactive commissioning, the introduction of fuel onto the site for the first time, active commissioning, commencement of routine operation, periodic safety reviews, and eventual defueling and decommissioning. At each stage the licensee is required to produce appropriate documentation to accompany the request for permission to proceed. This documentation is required to substantiate the licensee’s safety, security and environmental protection arguments. The major documents produced are the Pre-commissioning Safety Report (PCmSR), the Pre-operation Safety Report (POSr) and the Pre-decommissioning Safety Report.

License conditions

At the heart of the UK licensing regime is the power to attach Conditions (ONR, 2017) in the interests of nuclear safety and radioactive waste management. There are currently 36 standard Conditions attached to all nuclear site licenses. These Conditions are a mixture of prescriptive requirements and goal setting objectives. In the main, the Conditions aim to envelope all the activities that are needed to effectively manage nuclear safety and ensure the safe design, construction, commissioning, operation, maintenance and decommissioning of a nuclear facility or facilities on the site. The Conditions also cover the production, minimization, conditioning, treatment and storage of radioactive waste. The goal setting Conditions generally require the licensee to make and implement adequate arrangements to address specific issues such as the control of construction of a new plant, modifications of an existing plant, or the training of people with safety related responsibilities. Hence, although there is a standard set of Conditions for each nuclear licensed site, the licensee’s arrangements will differ depending upon the activities being undertaken on the licensed site. ONR is responsible for assessing the adequacy of the licensee’s arrangements and can, if appropriate, “freeze” the licensee’s arrangements so that the licensee cannot change the arrangements without the permission of the ONR.

Regulatory inspection and enforcement

In the UK, inspection and enforcement activities are carried out through the use of designated site inspectors. The UK does not have inspectors who are resident on a nuclear licensed site. Typically, a designated site inspector will spend 30% of his or her time at the site. Much of the site inspector’s remaining time is spent writing up visit reports, reviewing the licensee’s documentation submitted to seek permission to undertake specific activities on the site, and working with other site inspectors and technical assessors (ONR, 2019b).

The site inspector will follow a site inspection program that enables ONR to check the licensee’s compliance with the license condition arrangements for the site. Inspections may also take place at the licensee’s corporate headquarters and elsewhere,

including contractor's premises and manufacturing sites. ONR also uses "team inspections" on particular topics such as witnessing the annual demonstration emergency exercise or the readiness inspection prior to the commencement of active commissioning.

ONR has a range of enforcement tools in the case of licensee non-compliance. These range from formal letters expressing concern, legally enforceable improvement or prohibition notices that can be served on the licensee, and the option of increased regulatory scrutiny. ONR also has powers to direct the shutdown of an NPP and prevent its re-start without ONR's consent. For serious cases of non-compliance, ONR can submit evidence of its investigations to the UK's national prosecution services for prosecution in the courts. In the UK, failure to comply with nuclear laws is a criminal offence.

Case Study 2: Nuclear Regulation in Canada

Canada has a mature and comprehensive nuclear power program with around 15% of its electricity coming from nuclear power (WNA, 2019). Canada is a leader in nuclear research and technology, has developed and exported NPPs, and has uranium mining, nuclear fuel manufacture and radioisotope production facilities. Nuclear energy has been regulated in Canada since 1946 when the Canadian Government established the Atomic Energy Control Board (AECB). The AECB was charged to provide for the "control and supervision of the development, application and use of atomic energy and to enable Canada to participate effectively in measures of international control of atomic energy." In 1954 the AECB was given responsibility for the regulation of Canada's atomic research and development activities that were under the control of the newly formed Atomic Energy of Canada Limited (AECL). The Canadian Nuclear Safety Commission (CNSC) replaced the Atomic Energy Control Board on 31 May 2000.

Legal framework

The OECD Nuclear Energy Agency provides a comprehensive overview of nuclear legislation in Canada in its document: Nuclear Legislation in OECD and NEA Countries—Regulatory and Institutional Framework for Nuclear Activities—Canada (OECD, 2011a). A list of relevant Acts and regulations is given in <http://nuclearsafety.gc.ca/eng/act-and-regulations/index.cfm>.

Nuclear Safety and Control Act

The Nuclear Safety and Control Act (Canada, 1997) is a comprehensive piece of legislation governing the use of nuclear energy in Canada. The Act established the Canadian Nuclear Safety Commission to regulate the development, production and use of nuclear energy and the production, possession and use of nuclear substances, prescribed equipment and prescribed information. The Act covers Canada's international obligations relating to the use of nuclear energy, national security, health, safety and environmental protection, and non-proliferation.

The Act gives the CNSC extensive powers to regulate the nuclear industry and make regulations in a wide range of activities involving nuclear energy and materials including the transport of nuclear materials, other prescribed substances, nuclear equipment and nuclear technology.

General Nuclear Safety and Control Regulations

The General Nuclear Safety and Control Regulations (Canada, 2000a) support the Nuclear Safety and Control Act. These regulations set out the requirements relating to the licensing process including exemptions. The regulations describe the obligations of licensees including the requirements: to have sufficient qualified staff; to protect people, to protect the environment; to maintain the security of the site; and to publish health and safety information. The regulations also impose obligations on workers including the requirement to comply with licensee's arrangements to protect people, the environment and national security.

The regulations set out what are prescribed nuclear facilities, equipment and information; give details on reports and records to be produced by the licensee; and details of inspector's certificates.

Radiation Protection Regulations

The Radiation Protection Regulations (Canada, 2000b) set out the obligations of licensees and workers. A licensee is required to implement a radiation protection program; keep records of radiation exposure; designate nuclear energy workers; and provide information to workers on radiation exposure levels. Dose limits are described along with the obligations on licensees.

Regulator—Canadian Nuclear Safety Commission (CNSC)

The CNSC is an independent organization that reports to the Canadian Parliament via the Minister of Natural Resources. It is independent from the Canadian nuclear industry. The CNSC is responsible for the regulation of nuclear energy and materials: to protect health, safety, security, and the environment; to implement Canada's international commitments on the peaceful use of nuclear energy; and to provide information on regulatory matters to the Canadian public (CNSC, 2019). The CNSC may have up to seven permanent members including the President and Chief Executive. Decisions made by the CNSC are not subject to review by the Minister. The CNSC recovers almost 70% of the cost of its activities from fee-paying applicants and licensees.

The CNSC consist of the President, members of the Commission and ~800 staff members. It has four main branches. The Regulatory Operations Branch is headed by the Executive Vice President and Chief Regulatory Operations Officer. The other three Branches, namely the Technical Support Branch; the Regulatory Affairs Branch; and the Corporate Services Branch are each headed by a Vice-President. The Regulatory Operations Branch has four directorates that are responsible for Power Reactor Regulation,

Nuclear Cycle and Facilities Regulation, Nuclear Substance Regulation, and Regulatory Improvement and Major Projects Management. The Directorate of Power Reactor Regulation regulates the development and operation of Canada's NPPs.

Regulatory approach

The CNSC operates within a regulatory framework with a hierarchy that has the Nuclear Safety and Control Act at the top and supported by regulations, licenses and certificates, and regulatory documents. Regulatory documents are key to the CNSC approach, and they explain to licensees and applicants what they must achieve in order to meet the requirements set out in the Nuclear Safety and Control Act and its supporting regulations. In the development of its regulatory documents, the CNSC consults the public and other stakeholders.

The CNSC uses licensing as its main regulatory approach. The CNSC can only issue a license for a nuclear installation if it is satisfied that the applicant is qualified to carry out the activity that is to be licensed and that the applicant will, *inter alia*, make provision for the safety, security, and the protection of the environment. The CNSC can also impose any term or condition on the license that it considers necessary for the purpose of the Nuclear Safety and Control Act. Regulations are used to place requirements on the licensee (Canada, 2000a). Inspectors have the powers to enter and inspect nuclear facilities, nuclear powered vehicles, vehicles carrying nuclear substances, prescribed equipment, or prescribed information. Inspectors also have the power to order a licensee to take measures that are considered necessary, *inter alia*, for the protection of health and safety, the protection of the environment and the maintenance of national security (Canada, 1997).

The CNSC established a "vendor-optional" process to assess reactor facility designs prior to the formal submission of a license application. The aim of this process is to give a vendor the opportunity to evaluate whether its reactor design will meet Canadian regulatory requirements. The process is not part of the formal licensing process and unlike other countries, the CNSC does not certify the design. However, it is useful in identifying fundamental barriers to the licensing of new designs in Canada.

A new NPP requires licenses from the CNSC for: site preparation, construction, and operation. The CNSC is not involved in the site selection process but the license applicant must demonstrate that the proposed site will not pose an unacceptable risk to health, safety, security, and the environment. The applicant is also expected to consider the facility's entire lifecycle. When applying for a license to construct, the applicant must demonstrate that the proposed NPP design meets the regulatory requirements. In addition, the applicant must demonstrate that the proposed design will be safe over the intended lifetime of the plant. In the case of a license to operate, the applicant is required to demonstrate that, *inter alia*, it has an appropriate safety management systems that will ensure the safe and secure operation of the plant. The applicant is also required to show that the inactive commissioning program has been satisfactorily completed and the reactor is ready to accept its first fuel load.

Information on decommissioning plans and financial guarantees are required early in the licensing process in the initial application. A licensing basis is used to define the set of requirements and documents that set the boundary conditions for acceptable performance and include such things as the safety control measures and the documents needed to support the license. Once a license has been granted by the CNSC, the information and commitments submitted with the license application have a legal status in relation to the requirements placed on the licensee. The CNSC uses a "permissioning" approach that requires the licensee to seek approval or consent from the CNSC in certain circumstances such as permission to proceed past a pre-defined hold point.

The CNSC uses a flexible approach when it comes to specifying the license period for a particular facility. In the case of NPPs, the CNSC is moving to aligning the operating license period with the 10-year periodicity of the periodic safety reviews. At the end of life for an NPP, the CNSC's licensing strategy is to require the licensee to apply for a 10-year decommissioning license that will be subject to renewal. At the end of the decommissioning/dismantling of the NPP, the licensee will be required to apply for a license to abandon the site.

Licensing and enforcement

Throughout the licensing process the CNSC is required to carry out assessments of the licensee's activities, and in order to define the scope of these assessments the CNSC uses a risk-informed approach.

Licensees are responsible for on-site emergency planning. The licensee is required to prepare a detailed emergency plan that includes the provision for emergency exercises to test the readiness of staff at the NPP to respond effectively to emergencies. The CNSC observes these exercises to be satisfied that the licensees are managing and implementing their emergency response plans effectively. For emergencies that have offsite effects, the licensee is expected to work with the appropriate municipal government, the principal/territorial governments and the federal government. Offsite plans are exercised, and in some cases the CNSC participates. The CNSC also observes these offsite exercises to confirm that the emergency response plan has been adequately implemented.

The CNSC's regulatory framework is largely non-prescriptive with clear goals, objectives and requirements together with associated regulatory guidance. The CNSC's regulatory documents are continuously updated and aligned with international standards. The regulatory framework for siting, design and construction of NPPs aligns with the IAEA safety standards (CNSC, 2016). Within the Directorate of Power Reactor Regulation, there are four regulatory program divisions (RPDs), each division being focused on an NPP site. In each RPD, there are permanently situated CNSC resident inspectors who carry out the day-to-day site inspection activities to check compliance with the licensing basis for the facility (CNSC, 2016). Technical staff that are located at the CNSC's Head Office are assigned to each RPD.

Inspectors are authorized to carry out inspections to check that the licensee is complying with the CNSC's regulatory requirements which may include license conditions. The CNSC's compliance program is informed by risk, looks at the implementation

of international agreements, and takes into consideration the previous record of the licensee in relation to regulatory compliance. Various inspection techniques are used including individual and team inspections on specific topics. Team inspections are usually led by the site office inspectors and include multi-disciplinary specialists from the CNSC head office. The results of inspections are given to the licensee. The baseline inspection program for an NPP is scheduled over a 5-year period; but if the licensee's performance falls below CNSC expectations, risk management is used to identify areas where additional inspection activities should be focused. Inspectors have the power to undertake unscheduled inspections.

The CNSC has a range of enforcement tools that includes written notices, increased regulatory scrutiny, requests from the Commission for information, orders, licensing actions, prosecutions, and administrative monetary penalties. The choice of the regulatory action is guided by the safety significance of the non-compliance.

Case Study 3: Nuclear Regulation in France

France has the largest nuclear power program in Europe with some 58 reactors on 19 sites and which generates over 70% of France's electricity production. In 2015 France introduced a new Act on energy transition and green growth (TECV Act 2015-992), this Act aims, *inter alia*, to reduce the nuclear share of electricity production to 50% by 2025. In addition to its nuclear power program, France has a full fuel cycle capability with facilities for fuel manufacture, uranium enrichment, fuel reprocessing, plutonium recycling and radioactive waste management. Through the CEA (Commissariat à l'énergie atomique et aux énergies alternatives), France has a large nuclear research capability (OECD, 2011b).

Legal framework

The OECD Nuclear Energy Agency provides a comprehensive overview of nuclear legislation in France in its document: Nuclear Legislation in OECD and NEA Countries—Regulatory and Institutional Framework for Nuclear Activities—France (OECD, 2011b). Further details are given in France's Seventh National Report for the 2017 Review Meeting of the IAEA Convention on Nuclear Safety (France, 2016) and France's Eighth National report for the 2020 Review Meeting (France, 2019).

The hierarchy of the French nuclear safety legal and regulatory framework flows down from European Union Directives, laws enacted by Parliament, decrees and orders given by Government, and technical regulatory and individual resolutions from the nuclear safety regulator. The safety regulator also produces non-legally binding guides. The Acts specifically relating to Basic Nuclear Installations (BNIs) are codified in the Environmental Code. The BNI licensing and regulation system is underpinned by some of the provisions of titles I, IV and the provisions of title IX of book V of the Code underpin the BNI licensing and regulation system (France, 2016, 2019).

The nuclear transparency and safety Act, TSN Act 2006 made extensive changes to the BNI legal system. This Act created a legislative framework for BNIs, allowing the regulation of each life cycle phase, and enabling monitoring, and the application of sanctions. It also allowed the safety regulator, *Autorité de Sûreté Nucléaire* (ASN) to become an independent authority. Article 4 of the TSN ACT 2006 gives ASN responsibility for monitoring nuclear safety and radiation protection, particularly monitoring compliance with the general rules and specific requirements relating to nuclear safety. The TSN Act requires BNIs to be licensed.

The licensing system for BNIs was set in Decree Number 2007-1557. For a license to be given, ASN is required to give its opinion; and after a public enquiry has been held, a decree must be issued by the Ministers responsible for Nuclear Safety. The person responsible for the operation of the nuclear installation lodges the application for a license with the Ministers. The operator is then required to send copies of the license application and the supporting documents to ASN. The supporting documents are expected to include such things as: an impact assessment, a preliminary safety report and a risk management assessment. A plan for decommissioning of the installation and reinstatement of the site is also required.

The Ministers responsible for nuclear safety send this information to the Prefect in the "Département" in which the public enquiry is expected to take place. The Prefect will notify neighboring foreign states in the vicinity of the proposed nuclear installation of the opening of the public enquiry, and foreign authorities may participate if they wish. At the conclusion of the public enquiry, the Prefect sends the report of the public enquiry and his opinion to the Ministers responsible for nuclear safety. When the Ministers are satisfied a draft decree is sent to the operator. Once in receipt of the draft decree the operator may submit its observations within 15 days.

Order 7 February 2012

The Order of 7 February 2012 which entered into force on 1 July 2013, incorporated the "reference levels" developed by the Western European Nuclear Regulators Association (WENRA). This order significantly reinforced the BNI regulatory framework. It also provided the legal basis for ASN requirements relating to the "stress tests demanded of nuclear licensees following the Fukushima Daiichi accident." This order applies to BNIs from design through to de-licensing and sets out the concept of "integrated safety." The key areas covered by the Order are: the licensee's organization and responsibilities including technical capabilities, monitoring of contractors, policy on integrated safety, integrated management systems and public information; the demonstration of safety via IAEA standards and ASN technical directives; control of detrimental effects and impact on health and the environment; pressure equipment designed specifically for BNI; waste management; and emergency preparedness.

Energy Transition and Green Growth Act 2015–922 (TECV Act)

The introduction of the 2015 TECV Act made substantial modification to the nuclear legislative framework. The main provisions of the Act were to reinforce transparency and information to the public; reinforcement of the regulation of BNIs to include the regulation of the use of sub-contractors; and clarification of the organization of the ASN and IRSN roles in the oversight of nuclear safety.

Regulator—Nuclear Safety Authority (ASN)

The ASN is an independent administrative authority responsible for the regulation of nuclear safety and radiation protection in France (France, 2019). Whilst the French Government retains the power to stipulate general regulations relating to nuclear activities by decree or order, ASN has the power to issue regulatory resolutions to clarify these decrees and orders. ASN is an administrative authority and it therefore has to rely on the expertise of the French Institute for Radiation Protection and Nuclear Safety (IRSN) and various Advisory Committees for advice on technical issues.

At the head of ASN is the Commission that has five Commissioners including the Chairman. The Chairman and two Commissioners are appointed by the French President; one commissioner is appointed by the president of the National Assembly and the other Commissioner is appointed by the president of the Senate. Each Commissioner is appointed for 6 years. The role of the Commission is to define ASN's strategy and develop general policies relating to such things as regulation, inspection, transparency, emergency management and international relations. The Commission submits ASN opinions to the Government and issues ASN resolutions.

The Director General (DG) of ASN reports to the Chairman of the Commission. The DG manages ASN's Head Office and 11 Regional Divisions. Three Deputy Director Generals, the Head of Cabinet, and the Chief Inspector report to the DG. Within the Head Office there are 9 Thematic Departments, an Office of Administration, a Management and Expertise Office, and a Control Support Office. The 9 Thematic Divisions cover: Nuclear Power Plants; Nuclear Pressure Equipment; Transport and Sources; Waste, Research and Fuel Cycle Facilities; Ionizing Radiation and Health; Environment and Emergencies; International Relations; Communication and Public Information; and Legal Affairs. The 11 Regional Divisions conduct most of the direct oversight of nuclear facilities, radioactive material transport, and small-scale nuclear activities.

At the end of 2018, ASN had a total workforce of 516 staff, 289 in the Head Office and 289 in the Regional Divisions and 1 abroad. In 2018 ASN's total budget was €84.45M. ASN's costs are covered by the State's general budget. ASN relies on IRSN for technical expertise and hence, there is an additional regulatory cost of €84.3M to cover IRSN's regulatory support activities.

Technical Support Organization

IRSN is the ASN Technical Support Organization. A 5-year support agreement between ASN and IRSN is used to set out the technical support arrangements that are needed to support ASN's activities. Each year there is an agreed protocol that provides the more detailed nuclear safety and radiation protection priorities. IRSN dedicates around 400 staff to provide the technical support for ASN. The French Government funds IRSN's technical support activities that are dedicated to ASN. IRSN is an independent public and commercial organization. It is regarded as the public expert in the field of nuclear and radiological risks. IRSN contributes to the development of public policies in the areas relating to its expertise. IRSN also carries out research programs to enable it to maintain its technical expertise.

ASN Advisory Committees of Experts

As noted above, ASN relies on technical and scientific advice from a number of advisory committees. These committees report to the ASN Director General.

Other relevant stakeholders

There are a number of stakeholders that impinge on the activities of ASN.

The Parliamentary Office for the Evaluation of Scientific and Technical Choices (OPECST), informs the French Parliament on scientific and technical choices. The OPECST is assisted by a Scientific Council. Each year ASN presents a report on the state of nuclear safety and radiation protection in France to the OPECST.

The High Committee for Transparency and Information on Nuclear Security (HCTISN) is a body that was set up to enable matters relating to the risks associated with nuclear activities to be discussed in an open and transparent way. Questions concerning information about nuclear safety, its regulation or oversight can be referred to the HCTISN by the ministers responsible for nuclear safety, and others including the chairmen of the National Assembly and the Senate and the chairman of the OPECST. BNI licensees can also put questions to the Committee.

The Nuclear Safety and Radiation Mission (MSNR)

The MSNR prepares general regulatory texts in conjunction with ASN and under the jurisdiction of the ministers and coordinates individual administrative procedures. It also provides the secretariat for the HCTISN committee, and ensures consistency of regulatory texts between BNIs and other Installations that are classified for the protection of the environment (ICPE).

The French High Council for Technical Risk Prevention (CSPRT)

This Council assists ministers responsible for ICPE, nuclear safety and industrial safety. The Council considers draft regulations and questions submitted to it by ministers or ASN. The CSPRT gives its opinion where the law or regulations require.

Regulatory approach

The BNI legal system provides an integrated approach aimed at preventing or mitigating all risks to the public or the environment. It adheres to the four principles of environmental protection applicable to nuclear installations, namely: prevention, precaution, polluter-pays, and public participation.

ASN is responsible for ensuring that the licensee's responsibility for nuclear safety is delivered in compliance with regulatory requirements. ASN sets out the safety and radiation protection objectives to be met by the licensees. The licensee is responsible for producing the safety documentation that demonstrates how the objectives will be delivered. When satisfied ASN approves the adequacy of the licensee's means for achieving these objectives. The licensee is required to implement the approved measures. ASN conducts inspections to check the licensee's compliance with the approved safety measures at the BNI.

ASN may, on request from the licensee, provide advice on proposed safety options. ASN will generally ask an advisory committee to review the licensee's proposal. ASN requires certain activities to be authorized and for such activities, ASN carries out a review and assessment of documentation submitted by the licensee before the licensee is permitted to carry out the required activity.

ASN operates a graded approach to its regulatory activities. ASN appoints inspectors and the duties and functions of inspectors are set out in Article 40 of the TSN ACT and Decree 2007-831.

Licensing and enforcement

An applicant wishing to operate a BNI requires an authorization from the minister responsible for nuclear safety. The applicant can ask ASN for an opinion on the safety options for the plant. These options must then be presented in the form of an application that includes a preliminary version of the safety analysis report (RPS). The application which is known as the BNI creation authorization, is then sent to the minister responsible for nuclear safety. ASN reviews the application and when satisfied, it proposes a draft decree to the Government. The application may be subject to a public inquiry and consultation with the Commission of the European Union. As soon as the BNI creation authorization application is submitted, a local information committee can be created. However, this committee must be operational by the time the authorization is issued. On receipt of the RPS, ASN submits it to one of its advisory committees for review.

A BNI creation authorization decree (DAC) is signed by the Prime Minister and the minister responsible for nuclear safety. The DAC sets out the key characteristics of the facility, the period of the authorization, and the maximum time until facility commissioning. ASN defines the nuclear safety requirements relative to BNI design, construction and operation. Once the facility is constructed, the licensee requires an authorization from ASN to commence commissioning of the facility with nuclear materials. The application to commence active commissioning is sent to ASN and includes the updated safety analysis report for the facility. When satisfied with the licensee's application, ASN issues the authorization to commission the BNI.

Substantial modifications to the facility as defined in Article R.593-47 of the Environment Code must undergo a similar procedure to the BNI creation authorization application. For other modifications, ASN has the power to control the licensee's actions via authorization or notification depending upon the significance of the proposed modification.

ASN can adopt regulatory resolutions to clarify decrees and orders relating to nuclear safety. These resolutions are subject to ministerial approval. ASN has developed basic safety rules and guidelines on various technical subjects relating to PWRs and other BNIs. These are guides, and the licensee need not follow them provided the licensee can demonstrate alternative approaches to attain the safety objectives.

ASN's regulation and oversight of the licensee's activities at nuclear power plant BNIs includes oversight of nuclear safety, radiation protection, the protection of the environment and labor inspectorate duties. ASN undertakes regulation and oversight on a number of levels, namely, review and analysis of the licensee's documentation prior to authorizing activities and inspections during operation. Inspections are done on a sampling basis with the overall aim of checking that the licensee is delivering its responsibilities for nuclear safety, health and environmental protection.

If ASN inspectors observe non-compliance with safety regulations, enforcement measures are available to ASN including financial penalties up to a maximum administrative fine of €10 m for non-compliance with the provisions applicable to BNIs. ASN also has the power to provisionally suspend the operation of a BNI and require the implementation of necessary improvements to the licensee's activities. In addition, criminal infringements identified by inspectors are sent to the public prosecutor's office for review and action. Penalties on conviction can range from €7500 to €150,000 plus between 1 and 3 years imprisonment.

Case Study 4: Nuclear Regulation in Japan

Japan has a large, mature nuclear power program covering NPPs (20 PWRs and 31 BWRs) fuel fabrication facilities, spent fuel reprocessing facilities, radioactive waste treatment and storage facilities. Japan also has a substantial nuclear fission and fusion research program. As discussed in [Mizokami and Rempe \(2021\)](#), the events at Fukushima, Daiichi has significantly impacted Japan's nuclear program. At the time that this article was written, Japan has, or is in the process of decommissioning 27 reactors including

two research reactors (JAIF, 2019). Japan's long-term policy for nuclear power is to reduce the contribution from nuclear power to around 20% in 2030 and to reduce dependency on nuclear power as much as possible by 2050. The source of much of the information in this case study is the "Convention on Nuclear Safety National Report of Japan for 8TH Review Meeting," August 2019 (Japan, 2019) and the Nuclear Regulation Authority (NRA) website (NRA, 2020).

Legal framework

Nuclear law in Japan started with the Atomic Energy Basic Act (Japan, 1955). The Reactor Regulation Act was introduced in 1957 (Japan, 1957). More detailed descriptions of nuclear legislation in Japan are given in Japan (2015, 2019) and OECD (2017).

Atomic Energy Basic Act 1955 (as amended)

This Act had a number of objectives relating to the security of Japan's future energy resources; progress in science and technology and the promotion of industry through engagement in research and development. Its basic policy was to ensure the safe use of nuclear energy for peaceful purposes. The Act initially established Japan's Atomic Energy Commission (AEC) under the Prime Minister's Office (now the Cabinet Office). The AEC's role related to research and development and the exploitation of nuclear energy. The Science and Technology Agency (STA) provided the Commission's secretariat. This Act set the framework for government control of certain activities relating to nuclear energy including the control of nuclear reactors.

Act on the regulation of nuclear source material, nuclear fuel material and reactors (Reactor Regulation Act) as amended

The purpose of this Act was *inter alia* to provide the regulations for the installation and operation of nuclear reactors. It set out the licensing procedure and requirements for NPPs including the requirement for operational safety programs, and identified the minister and the government department responsible for licensing decisions. It specifies the requirements for the control of design, construction, operation and modification. It also provides for regulatory inspection and gives ministers the powers to rescind permissions.

Revisions to the legal framework

Following a review in 1978, several laws were amended including: the Atomic Energy Basic Act; the Law on the Establishment of the Atomic Energy Commission known as the Establishment Law; and the Reactor Regulation Act. The main changes to these laws were the creation of the Nuclear Safety Commission (NSC) and NPP licensing procedures as set out in the Reactor Regulation Law. The NSC had five Commissioners appointed by the Prime Minister, and the STA provided its secretariat. These new arrangements required Ministers when issuing permissions for nuclear facilities, to consider the opinions of the NSC. The licensing of commercial NPPs subsequently came under the control of the Nuclear and Industrial Safety Agency (NISA) part of the Ministry of Economy, Trade and Industry (METI). The Department of Transport regulated marine nuclear reactors. Research and fuel cycle facilities were regulated by the STA.

The 1999 accident at the JCO Tokaimura facility precipitated changes in the nuclear safety regulatory framework. In 2000, the NSC was strengthened, transferred to the Prime Minister's Office, and given additional regulatory oversight responsibilities. The Reactor Regulation Act was amended to strengthen nuclear safety requirements, and the Act on Special Measures Concerning Nuclear Emergency Preparedness (Nuclear Emergency Act) was adopted.

Following the accident at the Fukushima Daiichi NPP, the legal framework for nuclear energy and its regulation was reviewed. In 2012, the Atomic Energy Basic Act, the Reactor Regulation Act, and other related legislation were amended. A new Act that established a new nuclear regulatory body (Japan, 2012) and the Nuclear Regulation Authority came into force in 2013.

Act for Establishment of the Nuclear Regulation Authority as amended

This Act set up the independent Nuclear Regulation Authority (NRA) for the regulation of nuclear safety and safeguards for nuclear reactors and of other activities and facilities associated with refining of nuclear materials, fuel fabrication, enrichment, interim storage, reprocessing, and radioactive waste disposal. The NRA was set up under the Ministry of Environment to ensure its independence from the nuclear industry and those parts of government responsible for the promotion of nuclear energy. The Act provides the organizational structure of the NRA, the appointment and dismissal of Commissioners, the duty to report to the Japanese parliament, the National Diet, and the disclosure of information.

Regulator—Nuclear Regulation Authority (NRA)

The NRA is an independent regulator with the power to establish NRA ordinances to execute laws. It exercises control using its powers to grant, permit and approve nuclear related activities. The NRA also has the powers to carry out inspections and issue orders. A Commission comprising of a Chairman and four Commissioners sits at the top of the NRA. The Prime Minister with the consent of the Japanese Parliament (Diet) appoints the Chairman and the Commissioners. The term of office for the Chairman and Commissioners is 5 years. The Chairman of the Commission appoints the staff of the NRA.

The Commission is supported by a secretariat headed by the Secretary General. There are two Deputy Secretary Generals, one heading the Human Resource Development Centre and the other being the Deputy Secretary General for Technical Affairs (the Chief Engineering Officer). Within the Secretary General's Secretariat there is a Director General for Emergency Response and a Director General for Radiation Protection Strategy and Security. This secretariat hosts the:

- Divisions for Policy Planning and Coordination, Personnel, Budget and Accounting, and Legal Affairs;
- Departments for Regulatory Standards and Research and Radiation Protection which includes safeguards and security.

The Nuclear Regulation Department is separate from the Secretary General's Secretariat and is headed by the Director General for Nuclear Regulation. The Nuclear Regulation Departments hosts the:

- Division for Nuclear Regulation and Planning;
- Division for Licensing Nuclear Power Plants;
- Division for Licensing Research Reactors;
- Division for Licensing Nuclear Fuel Facilities;
- Division for Licensing for Earthquakes and Tsunami Measures;
- Division for Planning Coordination and Oversight;
- Division for Oversight of Nuclear Power Plants;
- Division for Oversight of Specified Oversight; and
- Division for Oversight of Nuclear Fuel Facilities and Research Reactors.

In addition to the above Headquarter functions, the NRA has 22 Regional Offices located near nuclear sites that undertake oversight activities relating to nuclear safety, emergency preparedness and radiation protection and the Rokkasho Safeguards Center carries out inspection of reprocessing facilities.

The Act that established the NRA provided for a number of Councils and Committees to be established under the NRA to provide additional sources of advice to the NRA. The Reactor Safety Examination Committee provides advice on nuclear safety matters; its members are appointed by the NRA on a part-time basis for a period of 2 years and can be reappointed. The Nuclear Fuel Safety Examination Committee provides advice on the safety of nuclear fuel and associated facilities. The NRA appoints its members on the same basis as the members of the Nuclear Fuel Safety Committee. The Radiation Council provides advice on radiation hazard. The National Research and Development Agency Council provides the NRA with advice on issues concerning research and development.

The NRA has a staff of around 1000. In the financial year for 2019 the NRA had a budget of 54.7 billion yen ([Japan, 2019](#)). NRA's funding is provided by the national budget.

Regulatory approach

The NRA's regulatory approach is based on regulatory requirements and licensing authorizations with the objective of ensuring the protection of the public and the environment. The NRA produces the regulatory requirements that industry must comply with and carries out oversight inspections to check that licensees are complying with the requirements. Regulatory requirements are developed on a facility specific basis. NRA sets the safety goals for facilities to achieve, and the regulatory requirements are intended to deliver the goals. To develop regulatory requirements, the NRA will normally establish "Study Teams" and make use of technical agencies and academic experts. For example, NPP regulatory requirements are set out in the "NRA Ordinance Prescribing Standards, for the Location, Structure, and equipment for Commercial Power Plants and their Auxiliary Facilities," known as the "Reactor Establishment Permit Ordinance." This Permit is part of the licensing process.

Licensing and enforcement

In the case of an NPP, a licensee is required to submit an application to NRA for the construction of a new NPP ([Japan, 2015](#)). This application is required to address, *inter alia*, the location of the proposed facility, the type, power and number of the NPPs to be installed, a construction plan, type of fuel to be used, and method for spent fuel disposal. Typical documents required to support the application include description of the safety design. The NRA will carry out a "Conformity Review" before granting the permit; and the NRA must seek the opinion of the Atomic Energy Commission to confirm that the facility will only be used for peaceful purposes.

Once an Establishment Permit has been given, the licensee is required to obtain approval for its construction plan. The construction plan will be expected to give a detailed description of the design for the reactor. NRA has powers to control modifications during the construction process. NRA inspectors also examine key components, systems and structures prior to operation of the NPP, including nuclear fuel assembly fabrication. The licensee requires approval from the NRA for its "Operational Safety Programme" (OSP). The licensee's OSP is expected to address such things as: compliance with legislation, compliance with the OSP; safety culture; quality assurance; duties carried out by key operating personnel; training; operation; safety review of operation; environmental discharges; accident management; and maintenance. Before handling nuclear fuel, the licensee is required to produce a physical protection program and obtain NRA approval of its program. During the lifetime of the facility, the licensee is required to produce Periodic Safety Assessments (PSAs) at least every 5 years ([Japan, 2015](#)) and submit them to NRA. Licensees are required to report accidents and incidents on their facilities to the NRA. At the end of a facility's life, the licensee is required to produce a decommissioning plan and submit it to the NRA for approval.

In relation to emergency preparedness, the licensee must prepare a Nuclear Operators Emergency Preparedness and Response Plan (NOEPRP) before the commencement of NPP operations. The licensee is required to consult local governments in the vicinity of the facility when developing the NOEPRP and notify the NRA before operations begin. The licensee must also establish on-site emergency preparedness arrangements that include an emergency preparedness manager.

NRA inspectors undertake operational safety and physical protection inspections to check licensee compliance with regulatory requirements during the lifetime of the facility.

The NRA has the power to revoke a reactor installation permit if the licensee does not start operation within 5 years of obtaining the permit without good cause. NRA can also revoke a reactor installation permit or order the shut-down of a power reactor for a period of up to 1 year if the licensee violates the provisions of the Reactor Regulation Act. The NRA also has the power to require the licensee to improve safety if there is clear non-compliance with regulatory requirements.

There are penalties for non-compliance with the Reactor Regulation Act. If a reactor is constructed without a permit or a reactor is not shutdown when ordered to do so by the regulator, the person responsible can be imprisoned for up to 3 years or fined not more than 3 million Japanese Yen. There are other penalties for non-compliance with the NRA Establishment Act concerning persons who interfere with NRA investigations. Under these circumstances, a person may be fined up to 300,000 Japanese Yen. In addition, the licensee can also be fined a similar amount.

Case Study 5: Nuclear Regulation in Russia

Russia has a major nuclear power program and operates several types of nuclear fuel cycle facilities. As of 2019, the Russian federation had 36 operating NPPs, including two fast breeder reactors, giving some 29 GWe of installed nuclear capacity (IAEA, 2019).

Legal framework

The legal framework for the regulation of nuclear safety in the Russian Federation is carried out on the basis of Federal Laws and by-laws (IAEA, 2016b). The principal laws relating to the regulation of nuclear energy is Federal Law No. 170-FZ on 21 November 1995—“On the Use of Atomic Energy” as amended, and Federal Law No. 3-FZ of 9 January 1966—“On the Radiological Safety of the Public” as amended. However there are numerous other laws that control the use of nuclear energy in the Russian Federation.

Federal Law No 170 of 21 November 1995 (as amended)—On the use of atomic energy

The main principles for the regulation of the use of atomic energy, as set out in the 1995 Act On the Use of Atomic Energy, as amended, are *inter alia*: to protect individuals, the public and the environment from radiation hazards; to establish the responsibilities of the state safety regulatory authorities; and the independence of the state safety regulatory authorities from the authorities that use nuclear energy (Russia, 1995). The main purpose of the act is to create a legal framework for the system of state management of the use of atomic energy and for the system of state regulation of safety in the use of atomic energy and to establish the rights, obligations and responsibilities of state authorities, local government authorities, organizations and other juridical persons, and citizens. The operating organization is held solely responsible for the safety of a nuclear facility. The 1995 Act as amended has a wide scope including NPPs and fuel cycle facilities. It applies to the design, construction, operation and decommissioning of nuclear facilities including NPPs and radioactive disposal facilities.

The 1995 Act, as amended, sets out the procedures for drafting rules and regulations relating to the safety of atomic energy facilities. Under this Act, the President of the Russian Federation has powers to make decisions on safety issues relating to the use of atomic energy and approve those juridical persons that can own nuclear materials and nuclear facilities. The Federal Assembly of the Russian Federation is given powers to adopt Federal laws concerning the use of atomic energy and approve budgetary allocations in order to finance atomic energy related activities. The Act also gives powers to the government of the Russian Federation to, *inter alia*, enact federal laws; establish the functions, working procedures, rights and duties of the state safety regulatory authorities; and take decisions on the design, construction, operation and decommissioning of nuclear facilities.

Government of Russia Ordinance No. 280 of 29 March 2013

This ordinance covers the regulation and licensing of activities in the field of the use of atomic energy.

Rostechndzor Order of 8 October 2014—Administrative Regulation on Providing the State Service of Licensing the Activity in the Field of the Use of Atomic Energy by the Federal Environmental, Industrial and Nuclear Supervision Service

This Regulation defines the administrative actions the regulator must carry out, including interactions with the license applicants, licensees and other state bodies during the licensing process.

Federal Standards and Regulations in the Field of the Use of Atomic Energy

The Russian nuclear safety regulator has endorsed numerous regulations and standards that relate to the use of atomic energy. These address such things as: the general safety provisions for nuclear power plants (NP-001-15); safety rules for the management of NPP radioactive waste (NP-002-15); procedures relating to emergencies (NP-005-16); requirements for physical protection systems for nuclear materials and nuclear installations (NP-083-15); and general provisions for the decommissioning of nuclear facilities (NP-091-14).

Regulator—Federal environmental, industrial and nuclear supervision service (Rostechndzor)

The nuclear safety Regulatory Body in Russia is the Federal Environmental, Industrial and Nuclear Supervision Service (Rostechndzor). Rostechndzor has the authority to endorse legal regulatory acts related to the uses of atomic energy such as:

- Federal standards and regulations;
- Procedures for work licenses;
- Requirements for the composition and contents of safety related documents;
- Procedures for the submission of safety related documents to Rostechndzor;
- Procedures for the review of safety cases for nuclear facilities;
- Procedures for permits for the discharge of radioactive substances; and
- Procedures for compliance assessment of products and processes during design, manufacture, construction, installation, and operation.

It also has the authority to *inter alia*:

- License activities;
- Grant permits to people to work in nuclear installations;
- Establish guidelines for the release of radioactive materials into the environment;
- Carry out compliance inspections at nuclear facilities;
- Ensure oversight of nuclear facilities in emergencies;
- Oversee physical protection at nuclear installations; and
- Oversee control of nuclear material accountancy.

The organizational structure of Rostechndzor that is related to nuclear safety (IAEA, 2016b) is headed by a Chairperson with a Deputy Chairperson responsible for each of the four Headquarter (HQ) Departments. The HQ Departments cover:

- Safety Regulation of NPPS and Research Nuclear Installations;
- Safety Regulation of Nuclear Fuel Cycle Facilities, Ship Nuclear Installations and Radiation Hazard Facilities;
- Special Security; and
- International Cooperation.

In addition to its HQ Departments, Rostechndzor has six interregional territorial departments for supervision of nuclear and radiation safety. It is also supported by two technical support organizations, namely the Federal Budgetary Institution “Scientific and Engineering Center for Nuclear and Radiation Safety,” and Federal State-Owned Unitary Enterprise for Safety. Russia’s Seventh National Report to the Convention on Nuclear Safety Review Meeting showed that Rostechndzor had around 150 HQ staff and some 850 staff in the interregional territorial departments. The activities of Rostechndzor are funded by the federal budget.

Regulatory approach

The regulatory approach in Russia is based upon the application of laws, ordinances, orders, standards, and regulations. Ordinances of the Russian Government set out detailed requirements. A revision of the federal standards and regulations relating to NPPS was carried out in 2015 to better align the Russian requirements with those of the IAEA safety standards. These standards and regulations are detailed and focused on a wide range of nuclear related activities, such as lifetime performance management, rules for the layout and safe operation of equipment, monitoring of welds, safety rules for the management of radioactive waste, and requirements for the justification of the strength and thermal mechanical behavior of fuel assemblies.

Rostechndzor uses orders for enforcement of: licensing actions, including suspensions and annulment; actions to be taken following inspections; reviews of safety cases; and qualification requirements of experts used by Rostechndzor. Rostechndzor also produces detailed guides, such as recommendations for writing a Level 1 probabilistic safety analysis (see Modarres and Kim, 2021) relating to external hazards, recommendations for conducting reliability analysis, and severe accident management.

Licensing and enforcement

Rostechndzor controls and monitors a licensee’s activities via granting licenses and permissions to undertake nuclear related activities, assessing documentation, inspections, and enforcement (Russia, 2014).

To obtain a license to construct an NPP, the applicant must submit a suite of safety justification documents. The suite of documents is expected to include a:

- Preliminary Safety Analysis Report;
- Quality Assurance Program (QAP) for the NPP;
- Detailed QAP for construction;
- Description of the reactor design and significant safety systems.
- Probabilistic safety assessments (Level 1);
- Description of the physical protection arrangements for the NPP; and
- Commissioning and initial start-up program.

The information provided should be sufficient to enable Rostechndzor to be able to gain an adequate understanding of the design and safety features of the NPP. A license will only be granted when Rostechndzor is satisfied with the adequacy of the safety justification documentation. The NPP design organization requires a design and engineering license from Rostechndzor.

Following the completion of construction, the licensee is required to submit documents to demonstrate nuclear and radiation safety prior to the application for an operating license. The submission is expected to include documents such as:

- Preliminary Final Safety Analysis Report;
- Commissioning program, including first criticality and initial start-up;
- Results of the first criticality and power start-up;
- Final Safety Analysis Report (updated with results of initial power operations);
- Level 1 and Level 2 probabilistic safety assessments;
- Accident mitigation instructions and beyond design basis accident management guidance;
- Quality assurance program for operation;
- Selection and training of NPP workers;
- Maintenance arrangements; and
- Physical protection.

Rostechndzor inspectors carry out readiness inspections of the NPP prior to the first criticality and prior to initial power operations. Rostechndzor will only grant an operating license when it is satisfied that the submitted documents demonstrate the safety of the NPP during routine operation.

During the lifetime of an NPP, Rostechndzor has the power to conduct continuous inspections, annual inspections and unscheduled inspections (IAEA, 2013). Continuous inspections are performed by the site resident inspectors. Comprehensive inspections are organized by the headquarters personnel and are carried out once every 3–4 years. Targeted inspections carried out by the Interregional Territorial Departments.

Rostechndzor is required to exercise its powers in a way that is commensurate with the potential danger of the facility (Russia, 1995). It has the power to issue instructions to the licensee to rectify identified breaches of mandatory requirements. Rostechndzor has the power to gather information on violations in connection with breaches of regulations and to forward this information to the appropriate authorities to consider the institution of criminal proceedings. Penalties for violations have a ratio of 1:10 for individuals and legal entities (IAEA, 2013).

Summary

Individual countries have developed their own regulatory and licensing approaches. The five case studies described in this article illustrate that in spite of different legal systems and cultures, each country, in their own way, delivers nuclear safety regulation and licensing in ways that are consistent with international expectations set out in the Nuclear Safety Convention and supporting IAEA standards.

Introduction

Consequences of failures of complex systems, such as nuclear power plants, are significant and could lead to adverse effects on the public, environment, and the economy. Although failures of complex engineering systems are very rare, they are unavoidable. Probabilistic Risk Assessment (PRA), which is also known as Probabilistic Safety Assessment (PSA), is a model-based methodology to systematically identify scenarios of failure events that end with significant consequences, and then, quantify the frequencies and consequences for those scenarios to obtain risk estimates. While initially focused on estimating the likelihood of adverse outcomes such as reactor core damage and release of radioactive material to the environment, the PRA methodology has more recently become a life-cycle tool for informing regulation, design, manufacturing, construction, operation, maintenance, security, and decommissioning of nuclear facilities. Today, a broad spectrum of organizations in defense, energy, aerospace, health, and security industries rely on the PRA methodology for devising risk-informed life-cycle, regulatory, and policy decisions that are commensurate with the risks of the complex engineering systems. This chapter defines key PRA terms, the overall methodology steps, and the uses of its results.

Definition

Probabilistic Risk Assessment is a systematic procedure for studying the safety and security of complex systems during design and operation. The PRA models interactions and failure events involving human errors, software failures, and hardware malfunctions that could potentially lead to undesirable states of the system. It also assesses the most significant contributors to undesirable outcomes of the system (i.e., consequences including human, environmental, and economic losses). The fundamental questions a PRA intends to address are defined by [Kaplan and Garrick \(1981\)](#) as:

1. What can go wrong in the system that could lead to exposure of hazards?
2. How likely is this to happen?
3. If it happens, what consequences are expected?

These are commonly referred to as the risk triplet. The PRA addresses the first question by identifying scenarios of events (a combination of failures of humans, software, and hardware) leading to exposure of radiological, physical, or chemical hazards. A hazard is any agent that can cause harm or damage to humans, properties, or the environment. In nuclear power plants, the primary hazard of

concern is the radiological sources contained in the reactor core and includes undesirable events such as core damage or containment failure that potentially can lead to a large release of radiation. To address the second question, the PRA uses probabilistic and statistical methods to estimate the likelihood of each scenario. Finally, to address the last question, the PRA also includes an assessment of the magnitude of health, safety, environmental, and economic consequences resulting from the hazard exposure for each scenario. The risk value (i.e., expected loss) of each scenario is often measured as the product of the scenario frequency and its consequence. The main result of the PRA is not the estimated risk value, but rather the identification of the nuclear plant components and failure events that significantly contribute to the risk value, including the uncertainties associated with such estimates. In the remainder of this chapter, major steps in conducting a PRA will be discussed.

Basic elements of PRA

The PRA evaluates risks associated with complex engineering systems by delineating a large number of event scenarios that lead to undesirable consequences (or end states) defined by the analyst. An event scenario consists of the following elements in general:

- Initiating event: An event that triggers abnormal condition in the systems, and that if not correctly responded to, may lead to undesirable consequences.
- Hardware events: Failure or unavailability of hardware components.
- Software events: Failure or unavailability of software components.
- Human error events: Errors of human operators or plant personnel.
- Nonrecovery events: Failures to recover failed or unavailable components.

If an initiating event occurs inside the plant or for a reason related to the plant systems, it is called an internal event, and the PRA for internal events is referred to as an *internal event PRA*. If it is caused by a reason outside the plant or beyond the plant systems, it is called an external event, and the PRA for external events is referred to as an *external event PRA* (e.g., tsunami PRA). Also, depending on the operating state of the plant when the initiating event occurs, the PRA is called a full-power PRA or a low-power/shutdown PRA.

Steps in conducting a PRA

Fig. 1 shows the steps in performing a full-scale PRA. Each step is further discussed in the sections that follow.

Fig. 1 Components of the overall PRA process. Adapted from Stamatelatos M and Dezfuli H (2011) *Probabilistic Risk Assessment Procedures Guide for NASA Managers and Practitioners*, 2nd edn. Washington, DC: National Aeronautics and Space Administration, NASA Headquarters, Office of Safety and Mission Assurance.

Objectives and methodology

The first step in a PRA involves a definition of the objectives of the analysis. There are varied objectives for completing a PRA, and among them, the most common ones include design improvement, demonstration of risk acceptability, design and operational decision support, regulatory and oversight support, and aging and system health management. Once the objectives are clarified, an inventory of possible techniques and scopes that are consistent with the specific objectives should be selected. This step provides the framework and road map for the analysis. For the inventory of different PRA techniques and scopes, see [Modarres \(2006\)](#) and [Rausand \(2013\)](#).

Familiarization and information assembly

It is crucial to assemble all the relevant information and data about the physical layout of the overall system (e.g., plant description and design blueprints), administrative controls, and maintenance and test procedures, as well as subsystems and barriers of any form embedded in the system design (e.g., physical barriers, human interventions to prevent a further degradation of the plant condition). A detailed inspection or walkthrough of the plant should be performed in the areas expected to be of interest and importance to the analysis (e.g., relevant to protection, prevention or mitigation of hazard exposure conditions). The following items should be performed in this step:

1. Identify major critical barriers in the form of structures, emergency systems, and human-based or other interventions.
2. Identify and explicitly describe dependencies in the form of direct and indirect physical connections among critical subsystems (or parts of the system). The result should be summarized in a dependency matrix (see [Modarres \(2006\)](#)).
3. Gather historical data and information in the form of past failures and abnormal events that have been observed in the plant being analyzed or other plants of a similar design. Such information would help determine the likelihood and frequency of events and ensure the inclusion of essential scenarios.
4. During the analysis, it is crucial to have a well-documented process of information assembly and update, including any PRA models and analyses previously performed for the plant.

Identification of initiating events

Initiating events are the first events that take the nuclear plant out of its normal operating condition and potentially start a scenario of events leading to hazard exposure. Those abnormal events or conditions that, if not correctly and timely responded to, could ultimately result in the event of core damage or a large release of radioactive materials. During the normal plant operation, failures of equipment, natural events, or other events from outside the plant, such as an external fire or a flood, may cause the plant to enter an off-normal or transient state. When a transient starts, there are two possibilities. First, the state of the plant could be such that no other function is needed to maintain a safe condition. Here, the term safe refers to a mode of operation where the chance of exposing hazards is negligible. In this case, inherently or passively provided barriers prevent any hazard exposure. The second possibility is a state wherein certain protective functions by system operations, or human actions are required to prevent hazard exposure. PRAs are mostly concerned with the second class of events.

One method for determining initiating events is to develop a functional block diagram of the systems involved in the normal operation of a plant. Each function can then be decomposed into its subsystems and components of the systems that, individually or in combination, realize those functions. The functional block diagram is used to trace the effect of failure events that lead to the loss of the critical normal operating functions, whereby a transient in the plant would follow.

An alternative method is the use of Failure Mode and Effect Analysis (FMEA) (see [Stamatis \(2003\)](#)). The FMEA is an inductive method of identifying initiating events and is mostly an experiential technique. In both of these methods, one can always supplement the set of identified initiating events with generic initiating events, if known. For example, see [Sattison and Hall \(1990\)](#) for these generic initiating events for nuclear power plants. In particular, the choice of external initiating events (e.g., earthquake, high wind, and external flood) are based on generic sources. The following should be followed as part of this step in the PRA:

1. Select a method for identifying initiating events. The aforementioned functional block diagram and FMEA are representative methods. For other methods such as master logic diagram, refer to [USNRC \(1983\)](#).
2. Using the method selected, identify a set of initiating events.
3. Group the initiating events that require the same mitigating functions to avert hazard exposure.
4. Add generic initiating events that are judged by the analysts to be important.

In nuclear power plants, two classes of initiating events are generally possible: transients and loss of coolant accidents. Transients represent initiating events that trigger an abnormal condition where the reactor coolant system is intact, and the reactor pressure boundary is not affected. Loss of coolant accidents are abnormal conditions where the reactor pressure boundary is compromised due to a break or an opening through which the coolant will be lost. A PRA typically involves dozens of transients (such as loss of electric power due to a grid failure or loss of the feedwater system due to a pump failure) and several loss of coolant initiating events (such as a small, medium or large loss of coolant accident depending on the size of the opening or break). Other initiating events

such as internal fires and floods that start inside the plant, or external events such as earthquakes and high winds that start from outside of the plant, are also important in nuclear plant PRAs and will be discussed later in this chapter.

Development of event scenarios

Development of event scenarios addresses one of the risk triplet questions discussed earlier, namely: what can go wrong? Its purpose is to develop a complete set of scenarios following the occurrence of an initiating event. The scenarios that describe the functional response of the plant to the initiating events are frequently displayed by event trees. In a PRA, two types of event trees can be developed: functional and systemic. The functional event tree uses mitigating functions as its heading (sometimes referred to as pivotal events). The primary purpose of the functional tree is for better understanding of the event scenarios at an abstract level. The functional event tree also guides the PRA analyst in the development of a more detailed systemic event tree. The systemic event tree reflects the scenarios of specific events (in terms of loss of barriers, human errors, failures of protective or mitigative systems). Examples of mitigative systems in nuclear power plants are emergency core cooling systems and containment cooling systems. An example of a protective system is the reactor shutdown system. Therefore, a systemic event tree fully delineates the overall plant response to an initiating event and serves as the primary tool for further analyses in the PRA. For detailed discussions on specific tools and techniques used for this purpose, see [Modarres \(2006\)](#). The following procedure should be followed in this step of the PRA:

1. Identify the mitigating functions for each initiating event.
2. Identify the human actions and hardware operations associated with each function, along with the specific circumstances of success or failure.
3. Develop a functional event tree for each initiating event.
4. Develop a systemic event tree for each initiating event, delineating the success conditions, failed conditions, initiating event progression phenomena, and end effects (i.e., outcomes or consequential losses) of each scenario such as core damage or a large release of radioactivity.

For specific examples of scenario development, see [Modarres et al. \(2017\)](#), [Rausand \(2013\)](#), and [Stamatelatos and Dezfuli \(2011\)](#).

Logic modeling

Event trees commonly involve approximate chronological events developed from left to right from the initiating events. The branch points in the event tree show occurrence of events (known as pivotal events) where a barrier either successfully works or not. Since these barriers (e.g., human actions, subsystem operations) rarely fail in general, a sufficient record of the barrier failure data may not be available. In such cases, logic-based system analysis methods such as fault trees can be used to estimate the frequency of barrier failures represented as pivotal events. The fault tree analysis is a deductive modeling approach and involves developing a logic model in which the barrier is systematically broken down into its components or segments (referred to as basic events) for which adequate failure or unavailability data exist. Once the fault trees are developed, the Boolean expressions representing their binary logic in terms of Boolean operators, such as OR, AND and NOT, are obtained. The failure probabilities of the pivotal events can then be quantified from the Boolean expression representing the minimal cut sets of the top event, see [Vesley et al. \(1981\)](#).

Fig. 2 conceptually displays integration (or merging) of the event tree and fault tree logic models. The event tree depicts scenarios of events following the initiating event of a large loss of coolant accident. In order to avoid undesirable consequences, the reactor should be successfully shut down, the lost coolant replenished by an emergency core cooling system, and the decay heat removed by a residual heat removal system. In turn, these pivotal events are modeled by fault trees, as mentioned earlier. These fault trees show the important combinations of hardware failures, human errors, or software faults that cause the corresponding pivotal events to fail. For more details about fault trees associated with the event headings of an event tree, see [Vesley et al. \(1981\)](#), [Rausand \(2013\)](#), and [Modarres et al. \(2017\)](#).

In principle, a fault tree can be developed as follows:

1. Develop a fault tree for each pivotal event included in the event tree headings for which actual historical failure data does not exist and with which a subsystem consisting of multiple components, or a combination of human actions is associated.
2. Explicitly model dependencies of a subsystem on other subsystems and dependencies among components. Common cause failures (CCFs) discussed later in more detail in this chapter involving implicit dependent failures of multiple redundant components can also be explicitly modeled in the fault trees. This topic will be further discussed later.
3. Include all potential and probabilistically quantifiable causes of failure in terms of hardware, software, test and maintenance, or human error in the fault tree.

Failure data collection, analysis and performance assessment

The second question of the risk triplet (i.e., how likely is it?) can be addressed by evaluating the frequency of scenarios. To perform this assessment, the reliability and availability of components and subsystems that contain or mitigate the hazards are estimated from data gathered as part of the first step of the PRA. One of the best means for predicting future reliability or availability of barriers

Fig. 2 A simple integrated event-tree and fault-tree model.

is past field experiences, and sometimes coupled with reliability life tests when limited, or no field data are available. For methods of how to assess reliability and availability of components, subsystems and human actions (as barriers in risk) and for generic failure probabilities, see [Atwood et al. \(2003\)](#) and [Modarres et al. \(2017\)](#).

The analysis of failure data consists fundamentally of the following steps: (1) collect generic data, (2) assess generic data, (3) statistically evaluate facility- or system-specific data, and (4) develop failure probability distributions using the facility- or system-specific data. Three types of events identified during the risk scenario definition and system modeling must be quantified for the event trees and fault trees to estimate the frequency of occurrence of sequences: initiating events, component failures, and human errors.

The essential data include the time of failures, repair times, test frequencies, test downtimes, and common-cause failure events and parameters. Further, uncertainties associated with such data must also be characterized. [Modarres et al. \(2017\)](#) discuss available methods for analyzing such data. [Mosleh \(1988\)](#) discusses the data analysis focusing on dependent failures. Establishment of the database to be used will generally involve the collection of some plant-specific data combined with the use of generic failure data when specific data are absent or sparse. For example, [Modarres et al. \(2017\)](#), [AIChE \(1989\)](#), [Atwood et al. \(2003\)](#), and [IEEE \(1983\)](#) describe generic data for electrical, electronic, and mechanical equipment. When events are so rare that no prior experience exists and no reliability tests such as accelerated life tests are possible, then the likelihood of such events should be estimated using expert elicitation. The following procedure may be carried out as part of the data analysis task:

1. Determine generic values of material strength or endurance, applied load and stress, failure times, and failures on demand for each item (hardware, human action, or software) identified in the PRA event tree and fault tree models.
2. Gather plant-specific data on hazard barriers, along with test and maintenance data.

3. Assess the frequencies of initiating events and the probabilities of failure events based on experience, expert judgment, or generic sources.
4. Determine CCF probabilities for similar items, primarily from generic values. However, when significant specific data are available, they should be preferably used.

Common cause failures

Dependent failures are significant in nuclear power plant PRAs and must be given adequate treatment to avoid gross underestimation of such failures in protective or mitigative systems. These failures could be due to common root causes and coupling mechanisms such as the same design deficiencies, failure mechanisms, or poor maintenance that increase the chance of the near-simultaneous failure of components. A class of dependent events called common cause failures have been shown to contribute significantly to the overall plant risk. There is no unique and universal definition for CCF. However, a fairly general definition of CCF is given by Mosleh (1988) as “a subset of dependent events in which two or more component fault states exist at the same time, or in a short time interval, and are direct results of a shared cause.”

The primary causes of dependency among a set of systems or components are explicitly described and modeled in the logic models of a PRA. However, CCFs are implicit dependencies. For example, functional and shared equipment dependencies are explicitly modeled in the system fault tree analysis, but other dependencies among identical barriers or equipment are collectively modeled using CCF models.

Several different parametric models have been used in estimating the CCF probabilities. A single-parameter model, i.e., the β -factor model, is the first parametric model applied to CCF events in risk and reliability analysis. Multiple-parameter models are used to obtain a more accurate assessment of CCF probabilities in systems with a higher level of redundancy. The Multiple Greek Letter (MGL) model and the α -factor model are two popular methods for evaluating CCF probabilities in PRAs. For more information, see Mosleh (1988).

Human reliability analysis

It has long been recognized that human error has a substantial impact on the reliability of complex systems. Accidents at Three Mile Island and Chernobyl clearly show how human errors can defeat safety systems and play a dominant role in the progression of accidents. According to Gertman et al. (2002), past PRA studies have revealed that more than 60% of the potential accidents in the nuclear industry are attributed to human errors.

To obtain an accurate measure of system reliability or risk, human error must be taken into account. Analysis of system designs, operational procedures, and post-accident reports shows that human error can be an immediate accident initiator or can aggravate the accident situation. Without incorporating human error probabilities (HEPs), the results of system reliability and failure analysis are incomplete and often underestimated.

To estimate HEPs, one needs to understand human behavior. However, it is challenging to fully understand and model human behavior. Literature shows that there is not a strong consensus on the best way to model all types of human actions, and thereby, quantify HEPs. The assumptions, mechanisms, and approaches used by any one specific human model cannot be applied to all human activities.

Human reliability analysis (HRA) is an essential element of the PRA process to determine HEPs. HRA can be generally performed as follows:

1. Definition: Ensure that all different types of human interactions are considered.
2. Screening: Select the human interactions that are significant to system reliability.
3. Qualitative analysis: Develop a detailed description of the significant human actions.
4. Representation: Select and apply techniques to model human errors.
5. Impact assessment: Explore the impact of the significant human actions identified in the preceding step on the system reliability model.
6. Quantification: Apply appropriate data to suitable human models to calculate probabilities for various interactions under consideration. The quantification includes assessment of the dependent human failure events.
7. Documentation: Document all information necessary for the assessment to be understandable, reproducible, and traceable.

A large number of different HRA modeling methods have been developed and applied to PRAs, and can be classified into the following categories:

1. Simulation methods: Maintenance personnel performance simulation (MAPPS), and Cognitive environment simulation (CES).
2. Expert judgment methods: Paired comparison, Direct numerical estimation (absolute probability judgment), Success likelihood index method (SLIM), and Integrated Human Event Analysis System (IDHEAS).
3. Analytical methods: Technique for human error rate prediction (THERP), Standardized Plant Analysis Risk-Human Reliability Analysis (SPAR-H) method, Human cognitive reliability (HCR) correlation, and Time-reliability correlation (TRC).

These HRA modeling methods have their own pros and cons. For more details on these techniques, refer to Modarres et al. (2017) and Kolaczowski et al. (2005).

Quantification

Quantification of risk requires that fault trees and event trees be integrated (merged) into a single Boolean logic model, and their events quantified to determine the frequencies of event scenarios and associated uncertainties in the final risk values. This integration depends somewhat on how system dependencies have been handled.

The quantification requires the generation of the so-called minimal cut sets that represent the combination of events which lead to the end states of the PRA model. Starting with fault tree models for the various systems or event headings in the event trees, and using probabilistic estimates for each of the events modeled in the event trees and fault trees, the probability of each event tree heading (or pivotal event often representing failure of a hazard barrier) is calculated (if the heading is independent of other headings). The fault trees for subsystems and support components (e.g., lubricating, cooling, or electric power) are merged where needed, and the equivalent Boolean expression representing each scenario in the event tree model is developed. The Boolean expressions are reduced to arrive at the smallest combination of basic failure events (the so-called minimal cut-sets) that lead to the undesired outcome (e.g., core damage) or hazard exposure (e.g., large release). If possible, all minimal cut sets must be generated and retained during this process. However, in large PRA models, this leads to an unmanageably extensive collection of terms and a combinatorial explosion. Therefore, the collection of cut sets is often probabilistically truncated (i.e., the cut sets are discarded based on the number of terms in them or based on the probability or frequency of the cut set).

To perform Boolean manipulation of the PRA logic models, software tools may be needed. The following steps are used to integrate and quantify the PRA models:

1. Merge corresponding fault trees associated with each failure or success event modeled in the event tree scenarios (i.e., combine them in a Boolean form).
2. Develop a reduced Boolean function for each scenario (i.e., truncated minimal cut sets).
3. Calculate the total frequency of each scenario.
4. Calculate the total frequency of all scenarios in all the event trees.

Three levels of PRA for nuclear power plants

A nuclear power plant typically consists of not only a nuclear reactor core where nuclear chain reactions occur for energy generation but also a containment enclosing the nuclear reactor. The design purpose of the containment building is to contain the escape of radioactive materials to the environment in case of an emergency.

Because of the defense-in-depth features of a nuclear power plant, the PRA is usually performed at three levels as follows (refer to Fig. 3):

- A Level 1 PRA estimates the frequency of accidents that cause damage to the nuclear reactor core. This is commonly called core damage frequency (CDF).
- A Level 2 PRA, which starts with the Level 1 core damage accidents, estimates the frequency of accidents that release radioactivity from the nuclear power plant.
- A Level 3 PRA, which starts with the Level 2 radioactivity release accidents, estimates the consequences in terms of fatalities or injury to the public, and undesirable consequences to the environment.

In particular, Level 2 PRA models various severe accident phenomena that could occur after core damage, such as hydrogen combustion, core concrete interaction, or steam explosion. Further, Level 2 PRA estimates source terms, namely, types and amounts of radioactive or hazardous material released to the environment following an accident.

Level 2 PRA is typically conducted in the following steps:

1. The accident scenarios identified in Level 1 PRA as leading to core damage are grouped into plant damage states (PDSs) based on similarities in the plant conditions following core damage.
2. Next, the containment event tree analysis is performed to identify the scenarios that challenge the integrity of the containment and lead to the possible releases of radioactive material to the environment.
3. For each scenario, source term analysis is carried out to determine the quantities of radioactive materials that escape to the environment.
4. Releases are grouped into the release categories, each having the same impact on the consequences (i.e., human, environmental, or economic losses).

From the results of Level 2 PRA, one can gain insights into the level of robustness of the containment in providing protection for severe accidents and the adequacy of the accident management systems in protecting the containment and mitigating a large release of radioactive materials. Since the full-scope Level 2 PRA requires considerable effort, a limited-scope Level 2 PRA is frequently performed instead focusing on the assessment of the so-called large early release frequency (LERF). LERF is defined as the sum of the frequencies of those accidents leading to the rapid, unmitigated release of airborne fission products from the containment to the environment occurring before the effective implementation of offsite emergency response and protective actions such that there

Fig. 3 Three levels of PRA for a nuclear power plant.

is the potential for early health effects (USNRC, 2009). LERF is determined similar to the Level 2 PRA process, by only focusing on accident sequences leading to large early release. In addition to the LERF, a broader metric called large release frequency (LRF) is also sometimes used as a risk metric depicting all large release scenarios of the Level 2 PRA.

Uncertainty and sensitivity analysis

In all facets of the PRA (e.g., frequencies of initiating events, probabilities of failure of components, human error probabilities, common cause failure models and parameters, and severe accident phenomena), uncertainties need to be addressed. In PRAs, uncertainties are primarily shown in the form of probability distributions. For example, the probability of failure of a subsystem or a hazard barrier may be represented by a beta or gamma distribution.

The process involves characterization of the uncertainties associated with the frequencies of initiating events, the probabilities of failure of subsystems (or barriers), the probabilities of all event tree headings, the strengths or endurances of barriers, the applied loads or incurred damages associated with the barriers, the amounts of hazard exposures, the consequences of exposures to hazards, and the sustained total amounts of losses. Other sources of uncertainties are in the models used, for example: the fault tree and event tree models; the stress-strength and damage-endurance models used to estimate failure or capability of some passive barriers; the probabilistic failure models for hardware, software and human actions; and the models to treat inter- and intra-barrier failure dependencies. Another important source of uncertainty is incompleteness of the risk models and other failure models used in the PRAs.

Once uncertainties associated with hazard barriers have been estimated and assigned to models and parameters, they must be “propagated” through the PRA model to find the uncertainties associated with the results of the PRA. Propagation is done using one of several available techniques, in which the most popular method used is Monte Carlo simulation. The results are then shown and plotted in the form of probability distributions. Steps in uncertainty analysis include:

1. Identify models and parameters that are uncertain and the method of uncertainty estimation to be used for each.
2. Describe the scope of the PRA and the significance and contribution of those elements that are not modeled or considered in the PRA.
3. Assess the probability distribution for each basic event modeled in the PRA.
4. Propagate uncertainties associated with the hazard barrier models and parameters to find the uncertainty associated with the risk value.

Fig. 4 Treatment of uncertainties in PRAs.

5. Present the uncertainties associated with risks and contributors to risk in an easy way to understand and in a manner visually straightforward to grasp. **Fig. 4** illustrates the uncertainty associated with the overall core damage frequency as a result of Level 1 PRA based on the input uncertainties which were propagated through the PRA logic model.

Sensitivity analysis is aimed at determining the significance of choice of a model or its parameters, assumptions, and significance of specific uncertain input parameters or variables to the final risk value calculated. The process of sensitivity analysis is straightforward. The effects of the input variables and assumptions in the PRA are measured by modifying them by several folds, factors or even one or several orders of magnitude one at a time, and measure relative changes observed in the PRA's risk results. Those models, variables, and assumptions whose change leads to a relatively significant change in the final risk values are regarded as "sensitive." A proper sensitivity analysis strengthens the quality and validity of the PRA results. Interested readers are referred to [Modarres \(2006\)](#) for more detailed discussions on sensitivity analysis.

Risk ranking and importance analysis

Ranking the elements of the system with respect to their risk or safety significance is one of the most important outcomes of a PRA. The ranking is merely arranging the elements of the system based on their increasing or decreasing contribution to the final risk values. There are several different importance measures in PRAs used for risk ranking in PRAs. For example, Fussell-Vesely, Birnbaum, Risk Achievement Worth (RAW), and Risk Reduction Worth (RRW) ([Modarres et al., 2017](#)) are identified as appropriate measures for use in PRAs, and all show the level of contribution of various parts of the PRA model to the final risk values. For additional discussions on the risk ranking methods, see [Azarkhail and Modarres \(2004\)](#). The following are the significant steps of importance ranking:

1. Determine the purpose of the ranking and select an appropriate importance measure that has a consistent interpretation for the intended uses of the ranked results.
2. Perform risk ranking and uncertainty ranking as needed.
3. Identify the most critical and vital elements of the system with respect to the final risk values and the total uncertainty associated with the calculated risk values.

Consideration of internal flooding and internal fire initiating events

Internal flooding refers to floods originating within the plant boundary. The internal flood PRA for a nuclear power plant evaluates the impact of internal flood as the cause of either an accident or a system failure in such a way that: (1) the fluid sources within the plant that could flood plant locations or create adverse conditions (e.g., spray, elevated temperature, humidity, pressure, pipe whip, jet impingement) or that could damage mitigative plant equipment are identified, and (2) the internal flood scenarios that could lead to hazard exposure are identified and quantified.

The following is a concise description of each technical element included in the internal flood PRA process ([AMSE/ANS, 2009](#)).

1. Define the physical boundaries of the analysis (i.e., the locations within the plant where flood scenarios are postulated), and divide the various volumes within that boundary into physical analysis units referred to as flood areas.
2. Identify and characterize the various sources of floods and equipment along with the mechanisms resulting in a flood or spray from these sources (e.g., amount of liquid and flowrates).
3. Develop flood scenarios involving flood source, propagation path(s), and the affected equipment.
4. Identify the expected plant response(s) to the selected set of flood scenarios and quantify the frequency of core damage or any radioactive release frequency.

The internal fire PRA analyzes accident scenarios associated with fires that might occur within the plant boundary. The following briefly describes those technical elements conducted as part of the internal fire PRA ([AMSE/ANS, 2009](#)).

1. Define the physical boundaries of the analysis (i.e., the locations within a plant where fire scenarios are postulated) and divide the various volumes within that boundary into physical analysis units generally referred to as “fire areas” or “fire compartments” including equipment located in them. Screen out areas and equipment which are not important.
2. Identify cables (and the equipment to which the cables are connected) that are required to support the operation of fire PRA equipment selected, and cables whose failure could adversely affect systems needed to respond to this accident.
3. Develop scenarios that reflect the plant response following a fire. Moreover, select scenarios that contribute to plant risk.
4. For each fire area, find the frequency of fires (expressed as fire ignitions per year) and screen out areas with low fire risk contribution.
5. Trace fire-induced cable failures and determine their impact on the plant equipment, systems, and functions included in the fire PRA response model.
6. Analyze operator actions needed for safe shutdown, including those called out in the relevant plant fire response procedures.
7. Quantify and present the resulting fire-induced CDF and LERF risk results. For further readings on this topic, see [EPRI and USNRC \(2005\)](#).

Consideration of external initiating events

As described earlier, external events initiate accidents from outside of the plant boundary. Examples of external events include earthquakes, high winds, external floods, external fires, lightning, and volcanic activity. Typically, a demonstrably conservative bounding analysis is performed for these external events to screen out insignificant ones. When the risk impact is judged to be potentially significant by the bounding analysis (e.g., conservatively estimating the hazard- occurrence frequency or the risk impact of the hazard, and then comparing the bounding estimate to a specific predetermined criterion), a detailed PRA may be performed for those selected or screened-in external events. Because seismic events are often found to be significant for nuclear plants, the way to conduct a PRA for this external event is briefly described herein.

The seismic PRA process consists of the following three steps ([AMSE/ANS, 2009](#)):

1. Estimate the frequency-seismic magnitude relationship (probabilistic seismic hazard analysis) associated with the plant site.
2. Determine the strength of structures, systems, and components (SSCs) concerning various ground acceleration levels (i.e., seismic magnitude) in terms of the conditional probability of failure given a specific acceleration level.
3. Develop seismic scenarios using the plant risk model for internal events with the application of seismic failure probabilities or frequencies for SSCs as well as human error probabilities in consideration of seismic situations. Calculate the risk values and contributors to each seismic scenario.

Interpretation of results

When the risk values are calculated, they must be interpreted to determine whether any revisions are necessary to refine the results and the conclusions. There are two main elements involved in the interpretation process. The first is to understand whether or not the final values and details of the scenarios are logically and quantitatively meaningful. This step verifies the adequacy of the PRA models and the scope of analysis. The second is to characterize the role of each element of the plant in the final results. This step highlights additional analyses of data and information gathering that would be considered necessary. The interpretation step is a continuous process with the acquisition of information from the quantification, sensitivity, uncertainty, and importance analysis activities of the PRA. The process continues until the final results can be best interpreted and used in the subsequent risk management activity.

Summary

Probabilistic Risk Assessment is a systematic procedure for studying and potentially improving the safety and security of nuclear power plants during design and operation. This chapter outlines the essential elements of the PRA technique used in the nuclear power industry and increasingly in other industries involving complex engineering systems. Engineers and safety inspectors can gain insights from the PRA to better focus resources on the hardware, software, and human elements of the system, maintenance, operations, and organizational factors that are most important to safety. Using the PRA results, safety, health and environmental regulators and other stakeholders can confirm the safety significance of enhancements and proposed changes to complex system design and operation. The PRA methodology has more recently become a life-cycle tool for informing regulation, design, manufacturing, construction, operation, maintenance, security and decommissioning of nuclear facilities.

Risk-informed regulation

Definitions

The question of “What is risk?” can be answered by the risk triplet:

- What can go wrong?
- How likely is it?
- What are the consequences?

The responses to these three questions may be qualitative or quantitative depending on the specific application and the availability of operational data and experience.

A “risk-informed approach” to regulatory decision-making represents a philosophy whereby risk insights are considered together with other factors to establish requirements that better focus licensee and regulatory attention on design and operational issues commensurate with their importance to public health and safety (US NRC, 1999).

Principles of risk-informed regulation

The US Nuclear Regulatory Commission (US NRC) has led the way internationally in the application of risk assessment and risk-informed regulation since the late 1970s and early 1980s. Specifically, the US NRC established Safety Goals for nuclear power plant operations in 1986 (US NRC, 1986). In brief, the Qualitative Safety Goals are to:

- Protect nuclear plants such that individual members of the public bear no significant additional risk to life and health.
- Ensure that plants do not cause significant societal risk to life and health and have risk comparable to or less than risks of other electrical generation technologies.

For practical reasons, these qualitative goals are translated into the following Quantitative Health Objectives (QHOs):

- For people living near a nuclear power plant, the ‘nuclear risk’ should be less than one-tenth of a percent (1/1000) of the overall risk of death from accidents and cancer experienced by the average member of the US population.

In subsequent implementation of the Commission policy statement, the NRC Staff demonstrated that core damage frequency (CDF) of 10^{-4} /year and large early release frequency (LERF) of 10^{-5} /year are acceptable surrogates for the early and latent QHOs (US NRC, 2007b).

In August 1995, the NRC issued a final Commission policy statement on the use of probabilistic risk assessment (PRA) methods in nuclear regulatory activities (US NRC, 1995). The statement adopted the following policy:

- The use of PRA technology should be increased in all regulatory matters to the extent supported by the state of the art in PRA methods and data and in a manner that complements the NRC's deterministic approach and supports the NRC's traditional defense-in-depth philosophy.
- PRA and associated analyses (e.g., sensitivity studies, uncertainty analyses, and importance measures) should be used in regulatory matters, where practical within the bounds of the state-of-the-art, to reduce unnecessary conservatism associated with current regulatory requirements, Regulatory Guides, license commitments, and staff practices. Where appropriate, PRA should be used to support the proposal for additional regulatory requirements in accordance with 10 CFR 50.109, Backfitting. Appropriate procedures for including PRA in the process for changing regulatory requirements should be developed and followed. This policy intends compliance with existing rules and regulations unless these rules and regulations are revised.
- PRA evaluations in support of regulatory decisions should be as realistic as practicable, and appropriate supporting data should be publicly available for review.
- The Commission's safety goals for nuclear power plants and subsidiary numerical objectives are to be used with appropriate consideration of uncertainties when deciding on the need to propose and backfit new generic requirements on nuclear power plant licensees.

In its approval of the noted policy statement, the Commission stated its expectation that implementation of the policy statement will improve the regulatory process in three ways: (1) foremost, through safety decision-making enhanced by the use of PRA insights, (2) through more efficient use of agency resources, and (3) through a reduction in unnecessary burdens on licensees.

Defense in depth

Defense in depth is an element of the NRC's safety philosophy that employs successive compensatory measures to prevent accidents or mitigate damage if a malfunction, accident, or naturally caused event occurs at a nuclear facility ([US NRC, 2018a](#)). The defense-in-depth philosophy has traditionally been applied in plant design and operation to provide multiple means to accomplish safety functions and prevent the release of radioactive material. It has been and continues to be an effective way to account for uncertainties in equipment and human performance and, in particular, to account for the potential for unknown and unforeseen failure mechanisms or phenomena that, because they are unknown or unforeseen, are not reflected in either the PRA or traditional engineering analyses. Nuclear power plant defense in depth is taken to consist of independent layers of defense (i.e., successive measures) to protect the public:

- Robust plant design to survive hazards and minimize challenges that could result in an event occurring,
- Prevention of a severe accident (core damage) if an event occurs,
- Containment of the source term if a severe accident occurs, and
- Protection of the public from any releases of radioactive material (e.g., through siting in low-population areas and the ability to shelter or evacuate people, if necessary).

Types of applications

A broad list of the types of risk-informed applications that have been employed in the United States as well as internationally include ([EPRI, 2019](#)):

- Evaluating the acceptability of a change to the plant design or operating practices,
- Comparing design alternatives,
- Optimizing maintenance strategies, including evaluating and managing risk for different plant configurations,
- Deciding what, if any, actions should be taken when new information comes to light regarding a plant's capabilities or the nature of the hazards to which a plant might be exposed,
- Evaluating the need for changes to improve plant safety during periodic safety reviews,
- Accounting for plant performance in determining appropriate regulatory oversight activities.

The above risk-informed applications can be more conveniently categorized into those applications affecting operating reactors, those impacting the design and licensing of new reactor concepts, and those processes common to both currently operating and new reactor designs.

Regulation and oversight of operating reactors

Regulations—Mandatory

Since the mid-1980s the US NRC has promulgated a number of regulations that have a strong risk basis. For example, the Anticipated Transient Without Scram (ATWS) rule under 10 CFR 50.62 was prompted by concerns regarding the reliability of the reactor protection system (RPS) and the consequences of anticipated operational occurrences without reactor scram ([US NRC, 2003a](#)). Precursor ATWS events at Brown's Ferry Unit 2 in 1980 and Salem Unit 1 in 1983 led to regulatory analysis which concluded

that additional ATWS safety requirements were justified. The ATWS rule required the installation of hardware to lessen the probability of ATWS events and to mitigate their consequences. The current fleet of Pressurized Water Reactors (PWRs) is now required to have equipment that is diverse, reliable, and independent from the RPS, to automatically initiate the auxiliary feedwater system, and to initiate a turbine trip under conditions indicative of ATWS. Boiling Water Reactors (BWRs) are required to have a diverse alternate rod injection system and a diverse recirculation pump trip that are reliable and independent from the RPS. BWRs have a standby liquid control (SLC) system to inject borated water into the reactor vessel, and the ATWS rule also specified a minimum SLC system injection rate and boron concentration.

The Station Blackout (SBO) rule under 10 CFR 50.63 was implemented based on several plant-specific probabilistic safety studies; operating experience; and reliability, accident sequence, and consequence analyses completed between 1975 and 1988 (US NRC, 2003b). SBO is defined as the complete loss of ac electric power to the essential and nonessential electric switchgear buses in a nuclear power plant. The SBO rule requires that nuclear power plants be capable of withstanding an SBO for a specified duration and of maintaining core cooling during that period. The specified duration is determined for each plant by comparing the individual plant design with factors that have been identified in NRC technical studies as the main contributors to the risk of core damage resulting from an SBO.

The NRC published 10 CFR 50.65 (commonly referred to as the Maintenance Rule) on July 10, 1991. The NRC's determination that a maintenance rule was needed arose from the conclusion that proper maintenance is essential to plant safety (US NRC, 2018e). The Maintenance Rule is based on the premise that there is a clear link between effective maintenance and safety as it relates to such factors as the number of transients and challenges to safety systems and the associated need for operability, availability, and reliability of safety equipment. Specifically, 10 CFR 50.65(a)(4) requires that before performing maintenance activities (including but not limited to surveillances, post-maintenance testing, and corrective and preventive maintenance), the licensee shall assess and manage the increase in risk that may result from the proposed maintenance activities. The scope of the assessment may be limited to structures, systems and components (SSCs) that a risk-informed evaluation process has shown to be significant to public health and safety.

Finally, 10 CFR 50.44 provides requirements for the mitigation of combustible gas generated by a beyond-design-basis accident (US NRC, 2007a). In existing light-water reactors, the principal combustible gas is hydrogen. In an accident more severe than the design-basis loss-of-coolant accident (LOCA), combustible gas is predominately generated within the containment as a result of the following factors:

- (1) fuel clad-coolant reaction between the fuel cladding and the reactor coolant, and
- (2) molten core-concrete interaction in a severe core melt sequence with a failed reactor vessel.

If a sufficient amount of combustible gas is generated, it may rapidly react with oxygen and increase pressure sufficiently to lead to a containment breach or a leakage rate in excess of technical specification limits. Additionally, damage to systems and components essential to continued control of the post-accident conditions could occur. Requirements are provided in 10 CFR 50.44 for combustible gas control in containments including atmosphere mixing, equipment survivability, oxygen and hydrogen monitoring, and other provisions depending on reactor type (e.g., BWR Mark I containment inerting) and operating versus future reactor designs.

Regulations—Voluntary

The US NRC has also issued guidance and policy statements that are voluntary in nature meaning that the licensee is free to implement the measure (or not) as an alternative to existing regulation.

Regulatory Guide (RG) 1.174 (US NRC, 2018a) describes the key principles and the overall process for risk-informed decision-making as it relates to changes to the plant licensing basis. This guidance may be augmented by application-specific guidance as necessary. Fig. 1 illustrates the relationship of the five key principles. These principles include:

- The proposed licensing basis change meets the current regulations unless it is explicitly related to a requested exemption.
- The proposed licensing basis change is consistent with the defense-in-depth philosophy.
- The proposed licensing basis change maintains sufficient safety margins.
- When proposed licensing basis changes result in an increase in risk, the increases should be small and consistent with the intent of the Commission's policy statement on safety goals for the operations of nuclear power plants.
- The impact of the proposed licensing basis change should be monitored using performance measurement strategies.

RG 1.174 provides Acceptance Guidelines for what constitutes a small increase in risk level using surrogate measures of CDF and LERF from the plant PRA model. These Acceptance Guidelines are reproduced in Figs. 2 and 3.

An important application is RG 1.178 which provides the guidance for risk-informed changes to the ASME-required in-service inspection of piping within nuclear power plants (US NRC, 2003c). Specifically, RG 1.178 can enhance overall safety by focusing inspections of piping at risk-significant locations and locations where failure mechanisms are likely to be present, and by improving the effectiveness of inspection of components by focusing on personnel qualifications, inspection for cause, and the use of multi-discipline review teams.

Another key risk-informed application is that of the surveillance frequency control program (SFCP) under the Risk-Informed Technical Specifications Initiative 5b (NEI, 2007). The SFCP uses a risk-informed, performance-based approach for establishment of surveillance frequencies, consistent with the philosophy of RG 1.174. PRA methods are used to determine the risk impact of the revised intervals. Sensitivity studies are performed on important PRA parameters. A multi-disciplinary plant Independent Decision-

making Panel (IDP) is utilized to evaluate determinations of revised surveillance frequencies, based on operating experience, test history, manufacturer's recommendations, codes and standards, and other factors, in conjunction with the risk insights from the PRA. Use of an IDP-like decision-making forum can be seen in numerous risk-informed applications.

A growing regulatory application is that of risk-managed technical specifications (RMTS) under Risk-Informed Technical Specifications Initiative 4b (NEI, 2006). This program includes individual changes to technical specifications under RG 1.177 (US NRC,

2011). RMTS permits extension of the completion times, also referred to as the allowed outage times (AOTs), provided risk is assessed and managed within a configuration risk management program. Such a program is intended to maintain and improve safety through the incorporation of risk assessment and management techniques in technical specifications, while reducing unnecessary burden. Plants implementing this initiative are expected to use the same PRA analyses to support their Maintenance Rule (a)(4) programs. A deterministic backstop value is imposed to limit the completion time extension regardless of low risk impact. Results of implementation are monitored, and cumulative risk impacts are compared to specific risk criteria. Corrective actions are implemented should these criteria be exceeded.

The national standard, NFPA 805, specifies the minimum fire protection requirements for existing light water nuclear power plants during all phases of plant operation, including shutdown, degraded conditions, and decommissioning in order to protect the safety of the public, the environment, and plant personnel from a plant fire and its potential effect on safe reactor operations (NFPA, 2015). Fundamentally, NFPA 805 implements 10 CFR 50.48(c) as a risk-informed alternate fire protection rule and as a means of resolving long-standing fire protection issues. As of 2019, it is being implemented at about half of the US nuclear power plant sites.

RG 1.230 provides guidance on alternate requirements regarding pressurized thermal shock (PTS) in reactor pressure vessels (RPV) (US NRC, 2018b). The RPV in a nuclear power plant is exposed to neutron radiation during normal operation. Over time, the RPV steel becomes progressively embrittled in the region adjacent to the core. If an RPV were to have a pre-existing flaw of critical size and certain severe system transients were to occur, this flaw could propagate rapidly through the RPV, resulting in a through-wall crack. The severe transients of concern, known as PTS events, are characterized by rapid cooling (i.e., thermal shock) of the internal RPV surface that may be combined with repressurization. The simultaneous occurrence of critical-size flaws, embrittled steel, and a severe PTS transient is a low probability event.

The original PTS rule was implemented when there were limited embrittlement data, and analytical tools were overly conservative. The alternate requirements are based on more comprehensive and realistic analysis methods, while still maintaining adequate safety margins. The application of the alternate requirements may help to extend plant lifetime or reduce unnecessary burden on plant operations.

NEI 00-04 (NEI, 2005b) provides guidance for the implementation of 10 CFR 50.69 regarding risk-informed categorization of SSCs and the application of NRC special treatment requirements. Special treatment refers to requirements beyond normal industrial practices that ensure the SSC can perform its design-basis functions. The 50.69 process makes use of the multi-disciplinary IDP as noted above. The approach allows plants to focus on those SSCs that have the most nuclear-safety significance rather than treating all safety-related SSCs as equally important. Fig. 4 illustrates the risk-informed safety categories (RISC). The benefits of implementing the program accrue, in part, by savings in the procurement process for RISC-3 components that no longer need to be subjected to the normal safety-related quality assurance program. However, RISC-3 SSCs must still be capable of performing their design-basis functions.

Oversight

The US NRC regulatory framework for reactor oversight is a risk-informed, tiered approach to ensuring plant safety (US NRC, 2018c). To measure plant performance, the reactor oversight process (ROP) focuses on seven specific “cornerstones” which support the safety of plant operations in broad strategic areas. These cornerstones include such focus areas as initiating events, mitigating systems, barrier integrity, and others. Additionally, there are cross-cutting elements such as human performance. Within each cornerstone, a broad sample of data on which to assess licensee performance in risk-significant areas is gathered from performance indicator (PI) data submitted by licensees and from the NRC’s risk informed baseline inspections.

	Safety-Related	Nonsafety-Related
	NEI 00-04 Categorization Process	
Safety Significant	RISC-1	RISC-2
Low Safety Significant	RISC-3	RISC-4

Fig. 4 Risk-informed safety classifications (RISC). NEI (2005b) 10 CFR 50.69 SSC Categorization Guideline. NEI 00-04, Revision 0, p. 4. Washington, DC: Nuclear Energy Institute.

An example of a risk-informed PI is the mitigating systems performance index (MSPI) (US NRC, 2005). The MSPI monitors the performance of selected nuclear power plant systems based on their ability to perform risk-significant functions. It provides a surrogate measure of change in CDF (Δ CDF) resulting from departures of component unreliabilities and train unavailabilities from established baselines.

Another risk-informed approach for systems and events not covered by PIs is the significance determination process (SDP) for inspection findings (US NRC, 2019). The SDP uses risk insights, where appropriate, to assist NRC staff in determining the safety or security significance of inspection findings identified within the seven cornerstones of safety at operating reactors. The inspection findings use a color-coded scheme for safety importance as follows:

- *Green* indicates a finding of very low safety or security significance,
- *White* indicates a finding of low to moderate safety or security significance,
- *Yellow* indicates a finding of substantial safety or security significance,
- *Red* indicates a finding of high safety or security significance.

When it is possible to quantitatively assess a change in risk resulting from a performance deficiency, the change can be associated with this color coding as depicted in Fig. 5.

The resulting safety or security significance of findings, combined with the results of the risk-informed performance indicator program, is used to determine a licensee's level of safety performance and the level of NRC engagement with the licensee.

The NRC defines 'incident investigation' under Management Directive (MD) 8.3 as a formal process conducted for the purpose of accident prevention (US NRC, 2014). The process includes gathering and analyzing information; determining findings and conclusions, including the cause(s) of a significant event; and disseminating the investigation results for the NRC, industry, and public review. Fig. 6 illustrates how quantitative information regarding the conditional probability of core damage resulting

from a reactor event is used to set the priority for inspections. (Note: AIT stands for augmented inspection team, while IIT represents incident investigation team.)

Design and licensing of new reactor concepts

New light-water reactor safety goals

The NRC has established expectations that new reactor designs achieve a higher standard of severe accident safety performance than currently operating designs (US NRC, 1985). As noted in the SRM on SECY-90-016 the Commission supports a goal of 10^{-4} /year CDF and 10^{-6} /year for large release frequency (LRF) for use by the staff in its assessment of evolutionary light-water reactors (LWRs) (US NRC, 1990). It should be noted that LRF used in the licensing of new reactors is closely related to LERF used in regulatory applications for operating reactors in that both metrics are associated with large radionuclide releases of the order of a percent or more of core inventory. However, LERF is associated with releases before the effective implementation of off-site emergency response and protective actions such that there is a potential for early health effects (ASME, 2009) whereas LRF does not specify timing of release.

Additionally, the Commission approved a conditional containment failure probability (CCFP) objective of 0.1 as a basis for establishing regulatory guidance for evolutionary designs.

Advanced reactor safety goals

The safety goals for new LWR designs are not necessarily applicable to many advanced non-LWR concepts such as high-temperature gas cooled reactors, liquid metal fast reactors, and molten salt reactor designs. In this regard, the 2008 NRC Policy Statement on the Regulation of Advanced Reactors (US NRC, 2008) provides more generalized Commission expectations:

‘...that advanced reactors will provide enhanced margins of safety and/or use simplified, inherent, passive, or other innovative means to accomplish their safety and security functions.’

More specifically, the 2008 Policy Statement identifies attributes that could assist in establishing the acceptability of a proposed advanced reactor design or the ability to license it, including:

- Reliable and less complex shutdown heat removal systems,
- Longer time constants before reaching safety system challenges,
- Simplified safety systems that reduce required operator actions,
- Reduced potential for severe accidents, and
- Considerations for safety and security requirements together in the design process.

Risk-informed applications for new reactors

The NRC staff engaged with external stakeholders in a series of tabletop exercises regarding the appropriateness of regulatory applications of risk assessment that were developed for the current fleet of reactor designs (US NRC, 2012). Specifically, the tabletop exercises tested various realistic performance deficiencies, events, modifications, and licensing bases changes against NRC policy, regulations, guidance and other requirements (e.g., technical specifications) that are or will be relevant to the licensing bases of new LWRs.

The exercises evaluated many of the widely applied regulatory applications of risk assessment including:

- Risk-informed in-service inspection of piping,
- Risk-managed technical specifications,
- Risk-informed surveillance frequency control program,
- 10 CFR 50.69, risk-informed categorization and treatment of SSCs,
- 10 CFR 50.65(a)(4), maintenance rule, and
- The acceptance guidelines and key principles in RG 1.174.

The NRC staff did not identify any potentially significant decreases in the enhanced safety margins for new LWRs resulting from the implementation of the above regulatory applications. For several of these programs, the staff identified some potential regulatory and implementation issues that would need to be addressed, such as the lack of plant-specific operating experience.

The NRC staff and industry also engaged in a series of tabletop exercises related to the ROP. A broad cross-section of well-vetted cases from actual SDP findings, MSPI data, and event response per MD 8.3 from the current fleet of reactors was assessed. The SDP tabletops indicated that the existing risk thresholds for determining significance of inspection findings are generally acceptable for new LWR designs. However, the existing process would not always ensure an appropriate regulatory response for degradation of passive components and barriers. Similarly, the tabletop exercises for event response demonstrated that the existing risk thresholds for invoking reactive inspections are adequate for new LWRs, and that thresholds could be crossed to invoke reactive inspections.

The case studies developed for the MSPI tabletops showed that the basic MSPI formulation would be largely ineffective in determining an appropriate regulatory response for new LWR designs with active safety features. Furthermore, a meaningful MSPI may not even be possible for passive safety systems using the current formulation of the indicator. Subsequently, the NRC staff has recommended to the Commission that the MSPI not be implemented for the AP1000 in the near future given the limited reactor performance data available for this relatively new design (US NRC, 2018d).

Construction SDP

The NRC established an ROP for new reactors under construction, presently, only the AP1000 reactor design. The construction significance determination process (SDP) under the ROP uses risk insights, where appropriate, to help NRC inspectors and staff determine the safety or security significance of inspection findings identified within the six cornerstones of safety at nuclear reactors that are under construction (US NRC, 2013). The construction SDP is a risk-informed process and the resulting safety significance of findings is used to define a licensee's level of safety performance in constructing the facility and to define the level of NRC engagement with the licensee.

Like the ROP for operating reactors, inspection findings during construction are assigned a color representing the significance of the finding. The color thresholds for the construction SDP were risk informed through the assignment of systems and structures by an expert panel based on risk achievement worth (RAW) values and other risk importance considerations. In addition, finding color thresholds are based on a qualitative measure of construction quality, which was defined through expert staff judgment. Thresholds for non-reactor safety SDPs were similarly developed using either quantitative risk evaluation methods or were risk informed through expert judgment of the staff.

The final determination of significance is similar in nature to that of operating reactors although for reactor construction the significance has more to do with issues regarding the quality of construction of key structures and systems as opposed to actual risk configuration and events during operations.

Licensing of advanced non-LWR reactors

As of July 2019, the US NRC continues to implement a long-term strategic plan for the licensing of advanced non-LWR designs including the development of guidance for a flexible non-LWR regulatory review process (US NRC, 2017).

The principles and methodology in NEI 18-04 (NEI, 2018) provide one acceptable method for informing the licensing basis and determining the appropriate scope and level of detail for parts of applications for licenses, certifications, and approvals for non-LWRs. Specifically, NEI 18-04 "presents a modern, technology-inclusive, risk-informed, and performance-based (TI-RIPB) process for selection of Licensing Basis Events (LBEs); safety classification of SSCs and associated risk-informed special treatments; and determination of DID adequacy for non-LWRs." As discussed in NEI 18-04, LBEs consist of the entire collection of event sequences considered in the design and licensing basis of the plant, which may include one or more reactor modules. They include Anticipated Operational Occurrences (AOOs), Design Basis Events (DBEs), Design Basis Accidents (DBAs), and Beyond Design Basis Events (BDBEs). Non-LWRs include, but are not limited to, molten salt reactors, high-temperature gas-cooled reactors, and a variety of fast reactors (e.g., sodium-cooled, lead-cooled, gas-cooled, etc.).

The TI-RIPB process described in NEI 18-04 is:

- Risk-informed to fully utilize the insights from systematic risk assessment in combination with structured prescriptive rules to address the uncertainties which are not addressed in the risk assessment. This approach can provide reasonable assurance that adequate protection is provided for public radiological protection.
- Performance-based to evaluate effectiveness relative to realizing desired outcomes that are achieved by using quantifiable performance metrics for LBE frequencies and consequences and performance requirements for SSC capabilities to prevent and mitigate events. This is an alternative to a prescriptive approach specifying particular features, actions, or programmatic elements to be included in the design or process as the means for achieving desired objectives.

Comparing design alternatives

Risk insights can be used to inform the design of new reactor concepts, or to enhance the safety performance of operating reactors. For example, the design of a new reactor concept may begin with no detailed specifications of the design beyond the reactor core and the heat transport mechanism. Existing regulations may dictate general requirements and, in some instances, more specific requirements, but the designer is generally at liberty to decide how to meet aspects of the DID philosophy and safety margins. This flexibility often includes the degree of diversity and redundancy of mitigating systems for anticipated operational occurrences, design basis events, design basis accidents, and beyond design basis events.

For operating reactors, new requirements in the form of Orders and regulations continue to be issued, e.g. response to the Fukushima accident. While meeting the minimum requirements of the regulation, the licensee may choose to integrate the required change with discretionary changes to more effectively enhance plant safety. Similarly, plant improvements to mitigate the consequences of fire implemented under NFPA 805 (NFPA, 2015) may also improve the risk profile of the nuclear power plant for other types of hazards and events.

Risk insights and reliability studies are often used to ensure that plant modifications do not result in undesired consequences. Thus, mitigating systems should be designed with sufficient reliability to perform their intended function when required, but not spontaneously actuate when not required (e.g., 2-out-of-4 actuation logic).

Finally, risk-informed approaches may be utilized to optimize plant operational performance through the appropriate balancing of capital, operating, and maintenance costs. Cost-benefit analysis may be utilized and is a key aspect of severe accident mitigation alternatives (SAMA) analysis (NEI, 2005a) for license renewal.

Introduction

The purpose of this chapter is to discuss the development of risk insights in analyzing the results from a PRA and their use in risk-informed decision making. This section includes a brief review of the role of risk metrics and risk importance measures to identify the principal contributors to risk and to evaluate the sensitivity of the risk levels to variations in input parameters and models. Representative examples of some of the most noteworthy risk insights about risk contributors and how those insights were different than insights from traditional deterministic safety analyses are provided. A second use of insights covered here is that in risk-informed decision making associated with changes to plant designs and operations to improve safety and to prioritize resources on areas most important to managing risk. Additional examples of risk insights derived from risk-informed decisions are included. The third and final category of risk insights covered in this chapter is their use to define and evaluate the safety case for advanced reactors by risk-informed decisions in the selection of licensing basis events, safety classification of SSCs, and evaluation of defense-in-depth adequacy. The chapter concludes with a perspective on the impact of use of risk insights derived from PRA and PRA applications on the level of safety exhibited by operating and advanced reactors.

Evaluating the results of a PRA for risk insights

Examples of risk insights from PRAs

During the first two decades of PRAs on nuclear power plants, starting with the Reactor Safety Study (RSS) (USNRC, 1975), a significant body of work was accumulated in the performance of Level 3 PRAs.¹ Some key insights from this early work were reviewed in (Fleming, 2003).

Many of the methods and risk insights that we still use today were introduced in that landmark study (WASH-1400), and shortly thereafter in industry, led to PRAs being performed for such plants as Zion, Indian Point, and Oyster Creek (Garrick, 1988). The accident sequences that were found to make the most important contributions to the risk of a severe accident were found not to be correlated to the design basis accidents (DBAs).² Hence, small break loss of coolant accidents were found to be much more significant to risk than those initiated by large pipe breaks. Moreover, the concept that conservative safety analyses of design basis accidents can establish an upper bound on the risk to public health and safety was refuted. In fact, the risks calculated in the RSS were found to be completely determined by severe core damage accidents that are more severe than the DBAs. Although it was obvious that the consequences of a severe core damage event would exceed those of a design basis event, a key insight here was that the frequency of severe core damage events was much higher than expected using traditional deterministic approaches to safety.

¹A Level 1 PRA is limited in scope to determine the core damage frequency (CDF); A Level 2 PRA expands the scope to estimate the frequencies and radioactive material release source terms from a severe accident; and a Level 3 PRA extends the risk assessment to include a quantification of the offsite consequences of releases on public health and safety and property damage (USNRC, 1983).

²DBAs are accident sequences that are analyzed in the reactor license applications. They are postulated in a conservative manner so as to bound the consequences of accidents deemed credible. They are selected based on qualitative judgments of likelihood and their consequences are evaluated using conservative assumptions. In PRA, accidents more severe than the DBAs are defined and assessed in terms of quantitative estimates of their frequency and consequences using realistic assumptions.

Another key insight from the RSS and the early industry studies was that human errors make a significant contribution to the risk of a severe accident.

Traditional deterministic approaches to safety suggested that accidents require the postulation of failure of several independent systems and fission product barriers following an initiating event. Such thinking supported the qualitative judgments made in the deterministic framework of safety analysis that accidents more severe than the design basis accidents were so unlikely as to be negligible in the definition of the design basis and associated general design criteria. With the benefits of insights from application of PRA technology as well as lessons learned from various incidents and accidents such as the Browns Ferry Fire (Rempe, 2021) and the Three Mile Island accident (Skillman and Rempe, 2021), it is now clear to most PRA practitioners that severe core damage events are in fact much more likely than the DBAs. If one were to go back and assess the frequency of the DBA initiating events and realistic probabilities of the specific success and failure combinations that are assumed in the safety analysis reports, frequencies much lower than currently calculated core damage frequencies would result.

In the first PRA on LWRs, the Reactor Safety Study (RSS) was limited to internal events initiated at full power with only a qualitative evaluation of external hazards. While the concept of PRA levels was not introduced until publication of the PRA Procedures Guide (USNRC, 1983), the RSS can be classified as a Level 3 PRA. Almost immediately thereafter the scopes of PRAs performed on Zion, Indian Point, and Oyster Creek was expanded to address internal fires and floods, and seismic events. The first seismic PRA ever performed was that on Oyster Creek (Garrick, 1988). The next two decades of PRA development were primarily devoted to Level 3 PRA. This phase of PRA development was responsible for incorporating external hazards and eventually non-full power plant operating states. Risk insights that were developed in this phase of PRA have been summarized in Apostolakis et al. (2017), Fleming (2003), Garrick (1988), and USNRC (1990).

Examples of some of the most noteworthy insights are summarized in Table 1. The list of insights in this table is not intended to be comprehensive, but rather representative of the key insights from the extensive body of work in PRAs that have been completed

Table 1 Examples of risk insights regarding the principal contributors to risk in LWRs.

<i>Insight category</i>	<i>Insight</i>	<i>References</i>
Significant Contributions to Risk of Severe Core Damage	Risk of severe accidents is not bounded by that from the design basis accidents	Fleming (2003)
	Small loss of coolant accidents (LOCAs) exhibit much greater risk significance than large LOCAs	USNRC (1975)
	Support system faults, e.g., loss of offsite power and station blackout, loss of service water, component cooling water and safety system dependence on these systems are important risk contributors from the internal events hazard group	Apostolakis et al. (2017) and Garrick (1988)
	Common cause failures dominate the risk for accident sequences involving failure of redundant systems, e.g. anticipated transients without scram (ATWS), station blackout; independent failures in these system seldom if ever make significant contributions to risk	Mosleh et al. (1997)
	Significant risk importance identified in modeling dependencies of passive components on active systems, e.g. reactor coolant pump seal LOCAs resulting from cooling system faults	Fleming (1996)
	Importance of risk contributions identified from human errors of omission (e.g. failure of ECCS recirculation switchover following small LOCA) and commission (e.g., turning off high pressure injection during TMI-2 accident)	Apostolakis et al. (2017) and Kemeny et al. (1979)
	Significant risk contributions identified from accident sequences caused by seismic events on many sites	USNRC (1990)
	Significant risk contributions of accident sequences caused by internal fires and floods identified for selected plants	NSAC (1984)
	Unexpected finding that accidents initiated during low power and shutdown states more important than initially assumed	NSAC (1985)
	In general the level of risk and contributors to risk are plant and site specific	Garrick (1988) and Apostolakis et al. (2017)
Significant Contributions to risk of large early release and Level 3 risk metrics	Containments found to be effective in reducing the risk of a large release for current operating LWR designs	Apostolakis et al. (2017) and USNRC (1990)
	Dominance of containment bypass sequences involving interfacing systems LOCAs and steam generator tube ruptures for PWRs with large dry containments	PLG (1983, 1986a)
	The dominant accident progression bins for Mark I BWRs are early containment failure and drywell failure caused by drywell failure and loads at vessel breach (due to direct containment heating, steam blowdown, or quasistatic pressure from steam explosion)	USNRC (1990)
	Source terms for severe accidents found to be significantly less than those estimated in earlier PRAs for selected accident sequences	USNRC (2012)
	On sites with multiple reactor units, the risk of accident sequences involving two or more reactor units is significant for all sites and dominant for plants with shared systems and large risk contributions from external hazards	IAEA (2019), CNSC (2014), Fleming (2005), and PLG (1983)
	Risk reduction benefits of evacuation localized to 1-mile from the site boundary; extending the emergency planning zones from 1-mile to 10 miles achieves insignificant risk reduction benefit	PLG (1986b)

for operating LWR plants. These insights caused a major change in identifying the most important issues that contribute to nuclear safety in comparison with that which was associated with deterministic approaches to safety and inspired the movement toward risk-informed regulation culminating in many plant design and operational changes and associated license amendments using the decision making process described in USNRC Regulatory Guide 1.174 (USNRC, 2018).

One of most interesting insights from this early work was that the level of risk and principal contributors to risk was highly design and site specific. Indeed, the risk levels and contributors were not driven that much by reactor type or containment type, but more by details in how the plant was designed to protect against hazards, site characteristics, the vintage of the design, the engineering firms that built the plants, and other factors that determined the dependencies between front line safety systems and support systems, etc. For example the PRAs reviewed in Garrick (1988) and Apostolakis et al. (2017) included those on Zion, Indian Point, Diablo Canyon, South Texas, Seabrook, Sequoyah, Beaver Valley, and Watts Bar, all of which were Westinghouse PWRs with large dry containments. Yet the risk levels, risk contributors, and risk insights from these PRAs are all different and not highly correlated to reactor and containment type. Such insights were not available in NUREG-1150 for example because that landmark study selected only one plant from a specific reactor and containment type.

Another important insight from these early PRAs is that a full appreciation of the insights from a PRA requires the consideration and quantification of uncertainties (Kaplan and Garrick, 1981). It is important to sort out the role of the uncertainty in producing a PRA result so that the most effective risk management strategy can be devised. For risk contributions from many internal events, the uncertainties in the reliability performance of SSCs supported by both generic and plant specific data will tend to be very small. In these cases there is some confidence that strategies can be devised to improve the SSC availability or reliability to reduce the risk of these sequences. However, if the risk is dominated by a seismically induced failure of an SSC, such risk is most likely driven by uncertainties in the seismic hazard for that site in which case equipment reliability strategies would be ineffective in management of the risks.

As PRA technology evolved over the next two decades, additional important risk insights were obtained. The first efforts to assess the risk of accident sequences initiated during low power and shutdown (LPSD) plant operating states indicated that the risk of such sequences was significant and much greater than initially assumed (NSAC, 1985). This resulted from a combination of factors including the general relaxation of technical specifications during shutdown, extensive maintenance activities being performed during refueling outages, and difficulties in achieving containment isolation during such activities. With the benefit of risk insights from the early LPSD PRAs and the implementation of risk monitoring tools to track risk profile changes due to changes in plant configurations, many changes were made to manage the risks in all modes of operation. In parallel with these efforts, risk-informed changes to technical specifications were made using the decision making process in RG 1.174 to manage the risks of performing maintenance with the plant at power. As a result, an overall improvement in risk management was achieved in all modes of operation.

One of the limitations of practically all the PRAs that have been performed is application of a “one reactor at a time mindset” in which each reactor unit is assessed under the assumption that the other reactor units on the same site are safe. The first PRA that was performed that explicitly addressed the risks from accidents involving multiple reactor units concurrently was that on Seabrook Station (PLG, 1983). Even though the two reactor units that were originally intended to be built (the second unit was never completed) had dedicated containments and safety systems and sharing of systems was limited to the use of a common switchyard and ultimate heat sink, the risk of multi-unit accidents was found to be significant. Later some PRAs on sites with extensive sharing of systems found that multi-unit accident sequences dominated core damage frequency (CDF) and large early release frequency (LERF) (IAEA, 2019). The “one reactor at a time mindset” has been used to develop conclusions about satisfaction of the USNRC safety goals, even though the wording of the safety goal policy (USNRC, 1986) suggests otherwise. This mindset has been used to support single unit PRAs on multi-unit sites in which all the units not being analyzed are assumed, besides the one being investigated, to be safe. Based on the wording used in the safety goal policy, a case can be made that the safety goals should be applied to the site as a whole and that conclusions about the satisfaction of the safety goals would require the performance of a multi-unit PRA (Fleming, 2005). Hence, it can be easily seen that interpretation of safety goal policy is dependent on risk insights and the nature and scope of the PRA whose results are interpreted to develop those insights.

Risk metrics and methods for deriving risk insights

Risk insights are developed by presenting, interpreting, and analyzing the results of a PRA. In the decade or more that followed the RSS, most of the published PRAs were Level 3 PRAs; and by the end of the first decade, the PRAs were typically expanded to include a full range of internal and external hazards as well as both full power and low power and shutdown operating states (Garrick, 1988; Apostolakis et al., 2017).

In the most recent decade of PRA development for operating LWR plants, the scope of the PRAs has been focused on estimating CDF and LERF and adhering to the technical requirements in the ASME/ANS PRA Standard (ASME/ANS, 2013a). This standard has requirements for developing the risk models needed to estimate CDF and LERF for single reactor PRAs. These risk metrics are discussed more fully in Modarres and Kim (2021). Although much of the current focus in risk-informed applications of PRA makes use of these risk metrics, a more complete set of risk insights requires a full scope Level 3 PRA that addresses both internal and external hazards, all risk significant plant operating states, and accidents involving two or more reactors and sources.

The principal risk metrics and methods that are typically used to derive risk insights from PRAs are summarized in Table 2. The ASME/ANS PRA Standard focuses on the following risk metrics for determining what is risk significant and for delineating the risk contributors to CDF and LERF.

Table 2 Risk metrics and metrics used to develop risk insights.

Category	Metrics and methods	Role in developing risk insights	References
Level 3 PRAs	Exceedance frequency versus consequence levels ^a	Absolute statements of the integrated risks of various consequence metrics including population dose exposures, early and latent health effects, property damage, etc.	USNRC (1975) and USNRC (1983)
	Individual risks of early and latent fatalities	Metrics for evaluating risks against the NRC Safety Goal Quantitative Health Objectives (QHOs)	USNRC (1986)
	Matrix formalism for analysis of Level 3 PRA results	Systematic method for identifying the initiating events, accident sequences, plant damage states, and release categories that contributed to the overall risk	Kaplan (1982) and PLG (1983)
Level 1/LERF PRAs	Accident sequences grouped by common elements including initiating events, plant damage states, dependencies, and classes of contributors	Relative risk contributions of classes of accident sequences grouped by a common PRA model element	Garrick (1988) and Apostolakis et al. (2017)
	Rank ordered contributions from individual accident sequences and cutsets	Relative risk contributions of sequences and cutsets to CDF and LERF	Garrick (1988) and Apostolakis et al. (2017)
	Risk importance measures normalized against baseline risk measures	Relative risk contributions of basic events to CDF and LERF; sensitivities of CDF and LERF to changes in basic event probabilities and uncertainties	Van der Böst and Shoonakker (2001)
	Risk importance measured against fixed risk targets.	Quantifies increase in basic event, system, or other PRA modeling element necessary to reach a defined risk target	Johnson and Apostolakis (2009)
	Changes in CDF and LERF due to plant design and operational Changes	Basic metrics used to demonstrate that plant and operational changes due not result in significant changes to CDF or LERF	USNRC (2018)

^aThese are often referred to as Complementary Cumulative Distribution Functions (CCDFs).

- Percentage contributions to CDF and LERF from the accident sequences modeled in the PRA.
 - The collection of the accident sequences that make at least 95% of the CDF and LERF are required to be modeled using realistic assumptions so as to avoid the masking of risk insights using conservative assumptions. Meeting this requirement makes it possible to define the risk significant parts of a PRA model.
 - Individual accident sequences that contribute at least 1% of the CDF and LERF are defined as risk-significant accident sequences.
- Risk importance measures are used to determine which basic events³ make risk significant contributions to CDF and LERF.
 - If the accident sequences involving a basic event contribute at least 0.5% to either CDF or LERF, the basic event is defined as risk-significant
 - If either CDF or LERF increases by a factor of at least 2.0 when the basic is assumed to be failed, the basic event is classified as risk-significant.

By combining the basic events associated with specific SSCs and human failure events, the risk importance of SSCs and operator actions can be derived from the basic event importance measures.

Because the ASME/ANS PRA standard is limited to the above risk metrics, current PRAs and their associated risk insights are largely confined to those. Some pitfalls and potential misleading conclusions that be obtained by relying on these risk metrics are explored in the next section.

Pitfalls in developing useful risk insights from risk importance measures

Definitions, uses, and potential pitfalls in deriving risk insights from risk important measures have been reviewed in Van der Böst and Shoonakker (2001) and Fleming (1996). Risk importance measures such as F-V and RAW are defined for elements of the PRA model such as basic events. The basic events in turn are associated with systems, structures, and components (SSCs) and operator actions whose failures may contribute to risk. In recent PRA applications such as those to implement 10 CFR 50.69, (2008) these measures are used to establish the safety significance of SSC in which special treatment requirements for safety related non-safety significant SSCs may be relaxed. However, this practice of directly linking the risk importance of PRA model elements to ranking and

³Each accident sequences in a PRA is modeled as a sequence of basic events. The basic events represent initiating events and failures of SSCs and human actions that designed to mitigate the consequences of the initiating events. A given basic event may, and often do, appear on more than one accident sequence.

prioritizing activities associated with SSCs must be done with care so as to avoid certain pitfalls and derive the appropriate risk insights. These pitfalls are briefly discussed below with an illustrative example.

Lack of independence of importance measures

The risk importance measures for a set of SSCs or other PSA model elements are not independent parameters, e.g., the F-V importance for component X is not independent of the Fussell-Vesely parameter for component Y. This property is obvious from the mathematical definitions of the importance measures, but in many applications they are treated as though they were independent parameters. The importance assigned to each component is derived from the accident sequences in the PRA model in which that component, or the basic events assigned to that component, are modeled as failed. The basic event probabilities on these accident sequences may be reasonably assumed to be independent of other basic event probabilities. However, a given accident sequence involves other basic events not associated with that component that may belong to another component or an initiating event or operator action shared with other components along the same sequences. In addition, another key factor that contributes to any given sequence are the functional dependencies of one component on another. The lack of independence means that the risk importance measure for a component does not fully “belong to” that component and that there may be single issues that determine the risk importance measures for a whole host of components that are involved on the same accident sequences.

Individual character of importance measures

Risk importance measures examine the risk contributions and risk sensitivities one model element at a time. The combined impacts of changing the probability of two or more model elements cannot be reliably inferred from individual risk importance parameters. Any change made in the design, operation, or maintenance of the plant that can impact the risk is not accounted for in risk importance parameters computed for a baseline PSA. If care is exercised, one may be able to infer the risk impact of a few isolated changes from the risk importance measures. However, for many PSA applications, it is necessary to update the PSA to reflect the proposed change so that the cumulative effects of the change on two or more elements of the PSA model can be evaluated.

Risk importance of SSCs and PSA model elements that cause initiating events

There are several problems here; one already noted is the contribution that initiating events make to risk importance. In principle, fault tree models might be used for initiating event frequencies, and when this is done, the corresponding basic events can be ascribed a F-V importance. Indeed, one can easily ascribe importance to the event as a whole and this has been performed. When initiating events are modeled only as a basic event with an assigned frequency, the definition of the underlying causes become obscured as these causes are “buried” in the data. An additional problem is that RAW is not defined for initiating events since basic event frequencies are unbounded quantities, i.e., there is no technical basis for limiting the initiating event frequency to 1/year.

A frequent interpretation of the RAW for a given SSC is that it provides an indication of the risk impact of taking an equipment item out of service. While this interpretation may be reasonable in many cases, the full impact of the out of service condition is not always captured in the RAW measure. Taking a component out of service for testing or maintenance may imply a much higher likelihood of an initiating event due to human errors in performing these tasks, whose risk impact is not captured in the component RAW value.

Computational issues

The numerical values obtained in attempts to assign risk importance to equipment may be in error due to a variety of problems such as judgmental exclusion of the equipment from the PSA model, model truncation during the quantification process, implicit representation of the equipment that obscures the true risk impact, simplifying assumptions in the PSA model, scope limitations of the model, and other non-physical aspects of the PSA. Many of these issues are a bit more problematic for the RAW in comparison with F-V, since the argument to exclude the item from the model, however reasonable, might have been based on a low probability or low frequency argument. The possibilities for truncation need to be considered lest there be too sweeping a conclusion made from the results of a table of RAW values.

Masking risk insights regarding dependencies

One of the most important issues in deriving risk insights from risk importance measures is that the methods used to evaluate them seldom permit the identification of the risk importance of dependencies that are typically hardwired into the event tree/fault tree models. The following example described in [Fleming \(1996\)](#) provides an illustration of this pitfall.

For this example, the top ranking SSCs according to Fussell-Vesely (F-V)⁴ importance from an internal events full power PRA for an 3 loop PWR are shown in [Table 3](#) and some important information about the underlying accident sequences responsible for these F-V values in [Fig. 1](#).

There is a tendency in PRA applications to take results in the form of [Table 1](#) and conclude that such results can be used to prioritize actions to improve SSC reliability and availability that help determine the underlying basic event probabilities. If the F-V values

⁴Fussell-Vesely (F-V) importance is the fraction of the CDF associated with accident sequences in which the identified component is failed.

Table 3 SSC importance from a selected PRA.

Component	F-V importance
Diesel Generators (DGs)	0.24
Charging System Motor Operated Valves (MOV)s	0.11
Service Water System MOVs	0.11
Pilot Operated Relief Valves (PORVs) ^a	0.10
Turbine Driven Auxiliary Feedwater (TD AFW) Pump	0.059
4 Kilovolt Electrical Breakers	0.035
Reactor Trip (RT) Breakers	0.030

^aPORVs are valves that can be actuated by a pilot valve to reduce the pressure in a reactor coolant system.

**Fig. 1** Contributions to SSC importance by accident sequences involving reactor coolant pump seal LOCAs.

in **Table 1** are used for this purpose, there is a strong tendency to look at SSC availability and reliability issues that contribute to the basic event probabilities associated with these components. It turns out in this example that much of the risk importance listed in **Table 1** is associated with accident sequences involving reactor coolant pump seal LOCAs. This insight is gained by examining the accident sequences that contribute to the top ranking SSCs on the F-V importance table. While failures of the SSCs in question contributed to these sequences, the dependence of the integrity of the reactor coolant pump (RCP) seals on those SSCs is key to understanding why these sequences resulted in core damage.

Another risk insight that is gained from examination of the accident sequences underlying the F-V importance results is that the two MOV examples and the reactor trip breaker examples are associated with common cause failure of redundant MOVs and breakers. In addition, the TD AFW pump importance and much of the DG importance is from station blackout sequences initiated by loss of offsite power which overlap the RCP seal LOCA sequences. The DG importance is also dominated by common cause failures.

In **Fig. 2**, the importance information is rearranged to isolate out the risk importance of the RCP seal LOCA dependency, and revising the SSC values to exclude the contributions from RCP seal LOCA sequences (Fleming, 1996). This figure is much more valuable for developing risk management strategies for the top ranking F-V SSCs. It clearly shows how strategies to eliminate the RCP seal integrity dependence on active cooling systems would have a much greater impact in reducing CDF than trying to rely

Fig. 2 Revised SSC importance determined by isolating importance of RCP seal LOCA dependency.

on equipment reliability and availability priorities derived from [Table 3](#). In addition, the examination of the sequences contributing to the remaining importance results in [Fig. 2](#) would lead to the additional risk management strategies that would be effective in reducing CDF.

With a more complete understanding of the accident sequences and dependencies underlying the F-V values in [Table 3](#) the following risk management strategies would have the greatest opportunity to reduce CDF:

- Eliminate the dependence of the RCP seal integrity on active cooling system.
- Identify strategies to reduce the likelihood of common cause failures for
 - the charging system and service water system MOVs,
 - DGs, and
 - reactor trip breakers
- Identify strategies to reduce the frequency of loss of offsite power and transient events that challenge the ability of the plant to prevent station blackout and ATWS

Any of the above strategies is likely to be more beneficial to reducing CDF than by improving the reliability and availability of the SSCs in [Table 3](#). Such strategies would be second order effects.

The above example illustrates the pitfalls of the use of importance measures to directly associate them with equipment reliability and availability performance, without a detailed review of the underlying accident sequences and the system dependencies that are often hard wired into the PRA model and reflected in the sequences.

Use of risk insights in risk-informed regulation

An area where use of risk insights has arguably the greatest impact on the safety of operating LWRs is risk-informed regulation. Industry initiatives such as the EPRI PSA Application Guide ([True et al., 1995](#)) proposed that changes to the plant's operating licenses be permitted based in part on a demonstration that such changes would not have adverse impacts on risk. The now commonly used risk metric, Large Early Release Frequency (LERF), was proposed in this Guide as a means of addressing risk using CDF and LERF and obviating the need for a full scope Level 2 or Level 3 PRA. However, the key regulatory initiatives that made risk-informed regulation a reality were the NRC Commission policies on safety goals ([USNRC, 1986](#)) and use of PRA ([USNRC, 1995](#)), and the issuance of a regulatory guide, RG 1.174 ([USNRC, 2018](#)) and supporting guides that defined a risk-informed decision making framework for evaluating proposed changes to the licensing basis. This framework included an evaluation of the changes that would pose no significant risk increase, and would maintain defense-in-depth, safety margins, and adherence to the

regulations. RG 1.174 included numerical guidelines for demonstrating that changes in CDF and LERF brought about by the proposed license amendments would be sufficiently small. These guidelines were tied to the baseline results of the plant PRAs. One of the supporting regulatory guides was RG 1.200 (USNRC, 2009) which sets forth NRC guidance on the technical adequacy of the PRAs used for this purpose including the endorsement of industry PRA standards. More information on the use of this guide is found in Dube (2021).

The types of changes originally addressed in risk informed regulation included risk-informed changes to technical specification, inservice inspection of piping systems, inservice testing of safety related SSCs, containment leak-rate testing, and graded quality assurance. The last item on this list was expanded to an application involving a risk-informed reclassification of SSCs and relaxation of special treatment requirements for safety related SSCs that were found not be safety significant. This concept of safety significance was incorporated into the regulations in 10 CFR 50.69 and includes consideration of risk significance and preservation of defense-in-depth. Risk significance criteria for SSCs are based on those identified in the PRA standard (ASME/ANS, 2013) including those based on F-V and RAW importance. SSCs with F-V importance exceeding .005 and RAW exceeding 2.0, for either CDF or LERF, are regarded as risk significant in the standard.

Incorporating risk insights into advanced reactor design and licensing

For advanced non-LWRs under development, a technology inclusive, risk-informed, and performance-based methodology for supporting design and licensing has been developed as part of the industry led Licensing Modernization Project (LMP) (NEI, 2019). The LMP includes a risk-informed and performance-based decision making process for the following applications:

- Selection and evaluation of Licensing Basis Events (LBEs)
- Safety classification of SSCs and selection of SSC performance requirements
- Evaluation of defense-in-depth adequacy.

The LBEs that are selected and evaluated in this methodology address event sequences involving multiple reactors and non-reactor radionuclide sources.

The NRC has proposed to the Commissioners that the LMP methodology be approved to inform the content of license applications for future advanced non-LWRs (USNRC, 2019).

The LBEs in the LMP methodology are broadly defined to include all the events considered in the design, licensing, and formulation of the safety case for the reactor plant. Each LBE is a family of event sequences from a design specific PRA where event sequences are grouped according to similarity of the initiating event, plant response to the initiating event, and mechanistic source term for sequences involving a release of radioactive material from any source of radionuclides that has the potential for producing

Fig. 3 LMP frequency-consequence targets for evaluating LBE risk significance © 2019 Nuclear Energy Institute (NEI, 2019).

a risk significant LBE. Risk significance of an LBE is determined by comparing the frequencies, consequences, and uncertainties about the frequency and consequence estimates against a Frequency-Consequence (F-C) target. The risk significance criteria for LBEs are shown in Fig. 3.

The basis for the F-C Target in Fig. 3 is an interpretation of the NRC regulations and policies that relate to limits on the frequency and consequences of anticipated events and accidents. Details are discussed in NEI (2019).

There are four categories of LBEs in the LMP methodology as defined in Table 4. Importantly, LBEs may involve event sequences involving two or more reactors or radionuclide sources within the scope of the plant being evaluated. Hence, the frequencies are expressed on a plant-year basis where a plant may be comprised of multiple reactors and radionuclide sources. This requires the inclusion of these types of event sequences within the scope of the supporting PRA. A trial use PRA standard for advanced non-LWRs (ASME/ANS, 2013b) has been developed and is planned for a major upgrade in 2020 to incorporate feedback from pilot PRAs that exercised the trial use standard.

LMP also includes risk targets for the cumulative risks evaluated in a PRA that account for all the individual LBEs. These cumulative risk targets are selected to assure that annual dose limits from Anticipated Operational Occurrences do not exceed 100 mrem per year, and the NRC goal QHOs for individual risk of fatality from early and latent health effects (USNRC, 1986). Specifically the cumulative risk targets in NEI 18-04 include (NEI, 2019):

- “The total mean frequency of exceeding a site boundary dose of 100 mrem from all LBEs should not exceed 1/plant-year. This metric is introduced to ensure that the consequences from the entire range of LBEs from higher frequency, lower consequences to lower frequency, higher consequences are considered. The value of 100 mrem is selected from the annual cumulative exposure limits in 10 CFR 20.
- The average individual risk of early fatality within 1 mile of the exclusion area boundary (EAB) from all LBEs based on mean estimates of frequencies and consequences shall not exceed 5×10^{-7} /plant-year to ensure that the NRC safety goal QHO for early fatality risk is met.
- The average individual risk of latent cancer fatalities within 10 miles of the EAB from all LBEs based on mean estimates of frequencies and consequences shall not exceed 2×10^{-6} /plant-year to ensure that the NRC safety goal QHO for latent cancer fatality risk is met.”

SSC risk significance in the LMP methodology makes use of risk significance criteria that are anchored to fixed targets (NEI, 2019).

- “The total mean frequency of exceeding a site boundary dose of 100 mrem should not exceed 1/plant-year to ensure that the annual exposure limits in 10 CFR 20 are not exceeded based on the mean estimates of frequencies and consequences. An SSC makes a significant contribution to this cumulative risk metric if the total frequency of exceeding a site boundary dose of 100 mrem associated with LBEs with the SSC failed is greater than 10^{-2} /plant-year.
- The average individual risk of early fatality within 1 mile of the EAB shall not exceed 5×10^{-7} /plant-year based on the mean estimates of frequencies and consequences to ensure that the NRC safety goal QHO for early fatality risk is met. An SSC makes a significant contribution to this cumulative metric if the individual risk of early fatalities associated with the LBEs with the SSC failed is greater than 5×10^{-9} /plant-year.

Table 4 LBE categories in the LMP methodology © 2019 Nuclear Energy Institute (NEI, 2019).

Event type	LMP definition
Anticipated Operational Occurrences (AOOs)	Anticipated event sequences expected to occur one or more times during the life of a nuclear power plant, which may include one or more reactor modules. Event sequences with mean frequencies of 1×10^{-2} /plant-year and greater are classified as AOOs. AOOs take into account the expected response of all SSCs within the plant, regardless of safety classification
Design Basis Events (DBEs)	Infrequent event sequences that are not expected to occur in the life of a nuclear power plant, which may include one or more reactor modules, but are less likely than AOOs. Event sequences with mean frequencies of 1×10^{-4} /plant-year to 1×10^{-2} /plant-year are classified as DBEs. DBEs take into account the expected response of all SSCs within the plant regardless of safety classification
Beyond Design Basis Events (BDBEs)	Rare event sequences that are not expected to occur in the life of a nuclear power plant, which may include one or more reactor modules, but are less likely than a DBE. Event sequences with mean frequencies of 5×10^{-7} /plant-year to 1×10^{-4} /plant-year are classified as BDBEs. BDBEs take into account the expected response of all SSCs within the plant regardless of safety classification
Design Basis Accidents (DBAs)	Postulated event sequences that are used to set design criteria and performance objectives for the design of Safety Related SSCs. DBAs are derived from DBEs based on the capabilities and reliabilities of Safety-Related SSCs needed to mitigate and prevent event sequences, respectively. DBAs are derived from the DBEs by prescriptively assuming that only Safety Related SSCs are available to mitigate postulated event sequence consequences to within the 10 CFR 50.34 dose limits
Licensing Basis Events (LBEs)	The entire collection of event sequences considered in the design and licensing basis of the plant, which may include one or more reactor modules. LBEs include AOOs, DBEs, BDBEs, and DBAs

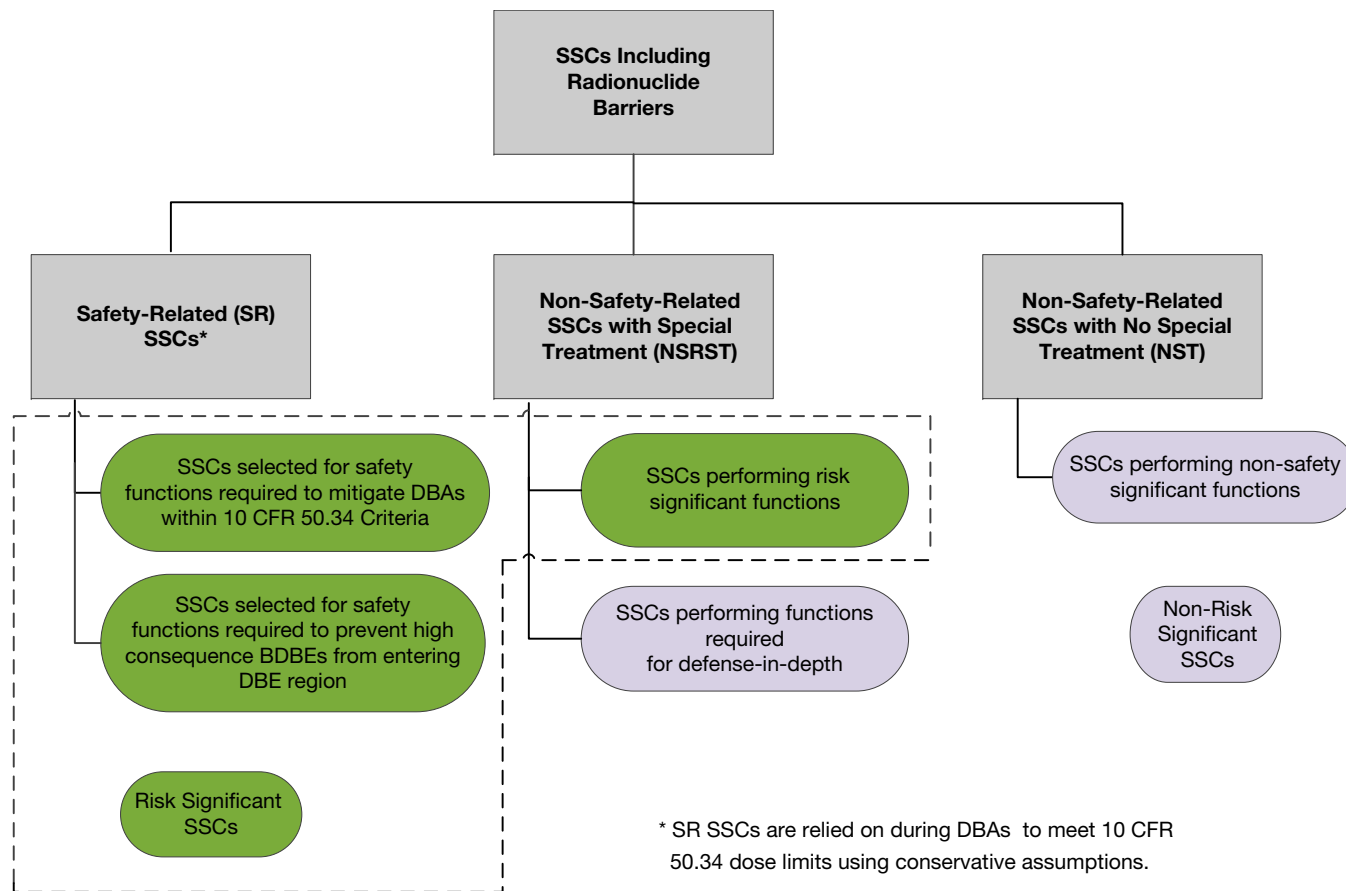

Fig. 4 LMP SSC safety categories and safety significant SSCs © 2019 Nuclear Energy Institute (NEI 18-04).

- The average individual risk of latent cancer fatalities within 10 miles of the EAB shall not exceed 2×10^{-6} /plant-year based on the mean estimates of frequencies and consequences to ensure that the NRC safety goal QHO for latent cancer fatality risk is met. An SSC makes a significant contribution to this cumulative risk metric if the individual risk of latent cancer fatalities associated with the LBEs with the SSC failed is greater than 2×10^{-8} /plant-year."

The use of mean values of frequency and consequence to establish the risk significance requires a full quantification of uncertainties. The uncertainty analysis is a key input to the identification of defense-in-depth protective strategies that are part of the process for establishing the adequacy of defense-in-depth. The defense-in-depth approach also addresses limitations of the PRA to achieve a balance consideration of deterministic principles and risk insights in demonstrating the safety case.

The risk significance criteria as well as guidelines for evaluating the role of the SSC functions in supporting the adequacy of defense-in-depth are used to classify the SSCs according to the safety significance of their functions as shown in Fig. 4.

An important element of the safety classification approach is that risk inputs and defense-in-depth evaluations are linked to the underlying event sequences in the PRA that are grouped into families represented in the LBEs.

The LMP methodology emphasizes that risk insights used for safety classification, and the evaluation of defense-in-depth adequacy, are fully integrated into the event sequence models in the PRA that addresses dependencies and interactions among the SSCs that cause initiating events and resulting event sequences as well as the characterization and analysis of uncertainties in the estimation of LBE frequencies and consequences.

This methodology has been subjected to several pilot applications that have confirmed its usefulness and applicability to a spectrum of advanced reactor designs including a high temperature gas cooled reactor, a fluoride salt high temperature reactor, a sodium cooled fast reactor, a molten salt reactor, and two microreactor designs involving the use of heat pipes. (USNRC, 2020).

Summary

In this chapter, the process of deriving risk insights from the results of a PRA has been described. The description has included examples of risk insights that were derived from early PRAs and a summary of how these insights have been and continue to be used to support risk-informed decision making for existing and advanced reactors. Risk metrics and methods of using these risk metrics to derive risk insights and support risk-informed decision making have been summarized. Limitations and pitfalls that must be appreciated to avoid misleading conclusions from the interpretation of risk importance measures such as F-V importance have been highlighted using examples.

Acknowledgments

The author acknowledges the following individuals who reviewed a draft of this manuscript and provided invaluable comments and shared insights: Dr. B. John Garrick, founder of the Garrick Risk Sciences Institute at UCLA and my mentor in risk analysis, Dr. George Apostolakis, former Commissioner of the U.S. Nuclear Regulatory Commission, currently Head of the Nuclear Risk Research Center, Japan and my colleague for many years, and Dr. Joy Rempé, Vice Chairman of the U.S. NRC Advisory Committee on Reactor Safeguards, also a colleague for many years.

Introduction

Nuclear power plants are like no other industrial facilities in the world in that the entire facility life cycle, including decommissioning is planned for from the very beginning of the plant's existence. In the United States, which has the world's largest operating commercial nuclear fleet, the Nuclear Regulatory Commission (NRC) requires – before a plant even begins operation – that the owner must establish a trust fund or other financial mechanism to ensure that there will be sufficient money to pay for the ultimate decommissioning of the facility. These same regulations require that the plant owner report to NRC every 2 years on the status of decommissioning funding. NRC's regulations are described in detail within this chapter. While practices vary in other countries, and initially some countries lacked the strong regulatory governance of decommissioning funding that exists in the United States, the concept of life of plant financial assurance has now become common worldwide.

What is meant by “ultimate” decommissioning of a nuclear power plant is also very clearly defined. National regulators, such as the US NRC, set requirements for the safe removal of a nuclear power plant from service including very stringent specification of the extent to which residual radioactivity levels must be reduced before the property can be released and its license terminated. At license termination, the site is remediated to a very small amount of radioactive material, with radiation levels at least 14 times less than natural background dose rates. After a plant's license is terminated, the site is no longer governed by the national regulator; however, State and local authorities often impose additional requirements for further site restoration which can include reducing radiation levels to an even smaller fraction of natural background dose rates.

There are three chapters related to the topic of Decommissioning in Section 4 of the Encyclopedia. This chapter presents an overview of US and international decommissioning strategies, regulatory requirements, status, and practices. The next two chapters provide examples of two U.S. plants that have proceeded with two of the more commonly used strategies: SAFSTOR (McCullum, 2021a) and DECON (McCullum, 2021b). The examples provided in these chapters illustrate some additional aspects associated with the decommissioning process, such as public involvement and public policy that influences the ultimate land use of the site.

Decommissioning strategies

The US NRC allows three strategies to achieve decommissioning (USNRC, 2018). These are listed as follows:

- DECON – The plant owner begins dismantling the plant and removing materials containing radioactive contaminants shortly after the facility ceases operations
- SAFSTOR – The plant owner defers dismantling and maintains the facility in a safe condition for several years after the facility ceases operation. This allows radioactivity to decay and the trust fund to grow before most of the work begins
- ENTOMB – The plant owner permanently encases radioactive contaminants on site in a structurally sound containment materials and monitors until radioactive decay allows the site to meet regulatory requirements for the license to be terminated

NRC regulations allow up to 60 years to complete the decommissioning process, this is based on up to 50 years in SAFSTOR followed by 10 years of DECON. To date, most plants in the US have pursued a combination of SAFSTOR and DECON with an initial decision being made to move into SAFSTOR with some DECON activities being conducted followed by a subsequent decision to move fully into DECON after some period of time in SAFSTOR. Often this decision is made concurrently with the transfer of either the license or the license and ownership from the utility that operated the plant to a company that specializes in decommissioning (see “U.S. decommissioning marketplace evolution” in this chapter). Recently there has been a trend, commensurate with these transfers, toward accelerating the transition into DECON.

Under the current regulatory framework, no US plant has ever opted for the ENTOMB option. However, prior to the formation of NRC, the Hallam Nuclear Station in Nebraska was decommissioned under the auspices of the Atomic Energy Commission using a similar strategy. The reactor vessel and other components remain buried under a grassy knoll at that site today awaiting site release in 2070 after sufficient radioactive decay has occurred (ANS, 2019a). Globally, the only unit currently using ENTOMB is Chernobyl Unit 4 in the Ukraine where that option was determined to be necessary due to the special circumstances that have existed since the reactor accident at that site in 1986 (Sich, 2021).

US decommissioning status

As of the date of this publication, in the United States 10 commercial nuclear power reactors have completed the decommissioning process¹ while an additional 10 have permanently ceased operations and are either in SAFSTOR or DECON. Tables 1 and 2 provide a summary of the status of these plants.

US decommissioning regulations

US NRC regulations are seen as the gold standard by regulatory authorities around the world. Because the US has also completed¹ the most decommissioning projects – approximately half of the power reactors that have reached the point of license termination are in the United States – the US regulatory framework for decommissioning is also the most tested. US decommissioning regulations have been effective at assuring safety and environmental protection throughout the life of each of the 10 completed projects listed in Table 1 above. As mentioned above, most other countries either already have or are moving towards requirements for decommissioning practices that mimic those in the United States.

In the US, the steps for commencing the decommissioning process are defined in 10 CFR 50.82 of NRC's regulations. In accordance with 10 CFR 50.82(a)(1), the process formally begins when a reactor licensee notifies the NRC that it has determined that it will permanently cease operations by submitting a written certification to NRC, within 30 days of having made this determination, in accordance with 10 CFR 50.4(b)(8). The licensee's first immediate task is to remove all fuel from the reactor vessel and place it in the spent fuel pool. Once this task has been completed, the licensee is required to submit a second certification – of permanent removal of fuel – in accordance with 10 CFR 50.4(b)(9). After NRC has formally docketed (e.g., accepted) both of these certifications, the licensee is no longer legally authorized to operate the reactor or return any fuel to the reactor vessel. At this point the decision to shut down the reactor has become irreversible.

The certification of permanent cessation of operations also starts the 60 year time period during which decommissioning must be complete. This is specified in 10 CFR 50(a)(3). The licensee may use any combination of SAFSTOR, DECON, or ENTOMB to accomplish this. 10 CFR 50(a)(3) also provides that, in certain special circumstances, NRC may consider extending the 60 year period only when necessary to protect public health and safety. Shutdown reactors which are co-located with operating reactors are generally considered an acceptable circumstance for extending the 60 year period as the conduct of demolition activities in proximity to an operating reactor could have adverse safety consequences.

Table 1 US Plants that have completed decommissioning (July 2019) (USEIA, 2017; USNRC, 2019).

<i>Plant</i>	<i>Location</i>	<i>Period of Decommissioning</i>
Pathfinder	Minnehaha County SD	1968–2007
Fort St Vrain ^a	Platteville CO	1989–1997
Rancho Seco ^a	Herald CA	1989–2009
Saxton	Altoona PA	1972–2005
Shoreham	East Shoreham, NY	1989–1992
Yankee Rowe ^a	Rowe MA	1992–2007
Trojan ^a	Columbia County OR	1993–2005
Haddam Neck ^a	Haddam Neck CT	1996–2008
Maine Yankee ^a	Wiscasset ME	1996–2005
Big Rock Point ^a	Charlevoix MI	1997–2007

^aSpent fuel remains stored at an Independent Spent fuel Storage Installation (ISFSI) on these sites. All land at the site is ready for release, but first the fuel must be removed and the ISFSI decommissioned.

¹The decommissioning process is considered complete when all plant structures and systems have been decommissioned such that the NRC license can be terminated. Spent fuel may remain on the site after this point in a separately licensed Independent Spent Fuel Storage Installation (ISFSI). In cases where an ISFSI remains on site the land can not be released for other purposes. So, in these cases, while the decommissioning is considered complete from a technical and regulatory point of view, from a public perception point of view it is not considered complete due to the continued presence of radioactive material on the site.

Table 2 US Plants^a currently undergoing decommissioning (August 2019) (NEI, 2019a; USNRC, 2019; Energy Daily, 2019).

<i>Plant</i>	<i>Location</i>	<i>Ceased operations</i>	<i>Current status</i>
Humbolt Bay	Eureka CA	1976	Initially placed in SAFSTOR, moved to DECON in 2008, scheduled for completion 2020
Lacrosse	Genoa WI	1987	Initially placed in SAFSTOR, moved into DECON in 2016 upon license transfer in 2016, expected completion 2020
Zion 1&2	Zion IL	1998	Initially placed in SAFSTOR, moved into DECON upon license transfer in 2010, expected completion 2020
San Onofre 1,2, & 3	San Clemente CA	2013	DECON
Crystal River Unit 3	Crystal River FL	2013	SAFSTOR, ownership transfer pending. Plant will move to DECON upon transfer
Kewaunee	Kewaunee WI	2013	SAFSTOR
Vermont Yankee	Vernon VT		Originally placed in SAFSTOR, ownership transferred in 2019 at which point plant entered DECON
Ft Calhoun	Ft Calhoun NE	2016	SAFSTOR
Oyster Creek	Forked River NJ	2018	Ownership transferred in 2019 at which point plant entered DECON
Pilgrim	Plymouth MA	2019	SAFSTOR, Ownership transfer pending, plant will move to DECON upon transfer
Three Mile Island	Middletown PA	2019	Unit 1 placed into SAFSTOR upon shutdown. Unit 2 Ownership transferred in 2019

^aDoes not include shutdown reactors on sites where there are still currently one or more operating reactors. Decommissioning of these reactors will be done in coordination with the future shutdown and decommissioning of the remaining operating unit(s).

A key requirement that must be met before decommissioning can begin is the completion, and submission to NRC, of the licensee's Post Shutdown Activities Report (PSDAR). In accordance with 10 CFR 50.82(a)(4), this report must describe planned decommissioning activities, the schedule for completing them, an estimate of costs, and a discussion of the environmental impacts associated with decommissioning (USNRC, 2019). The PSDAR must be submitted prior to or within 2 years following permanent cessation of operations. Although NRC approval of the PSDAR is not required, NRC does solicit public comments on the report and may ask questions of the licensee on its content (USNRC, 2019).

10 CFR 50.82(a)(5) specifies that the licensee may conduct no major decommissioning activities (as defined in 10 CFR 50.2) until both NRC has received the PSDAR and both the certification of permanent cessation of operations and permanent reactor defuel. 10 CFR 50.82(a)(6) and (7) place additional restrictions on the conduct of decommissioning and sets requirements for the reporting of any changes to the PSDAR (USNRC, 2019).

Throughout the decommissioning process, and until the license is terminated, safety is assured under the regulations of 10 CFR Part 20 (for radiation protection), 10 CFR Parts 50 and 73 (for everything else pertaining to the plant), and 10 CFR Part 72 (for spent fuel stored onsite in an Independent Spent Fuel Storage Installation (ISFSI)). The transportation of spent fuel away from the plant site is governed by 10 CFR Part 71 (USNRC, 2019).

NRC has recognized that there are some regulations in 10 CFR Parts 50 and 73, particularly in the areas of emergency preparedness and security, which should not be applicable at a decommissioning site because the potential for a reactor accident no longer exists. To date, relief from these unnecessary requirements has been obtained by the licensees applying for and NRC approving exemption and license amendment requests. However, this review and approval process is expensive. At the time of this publication, NRC had a rulemaking underway to codify an orderly transition from the full scope of operating reactor requirements to a more limited set of regulations appropriate for decommissioning, without the need for the licensee to submit these requests (USNRC, 2015).

NRC also carefully regulates both the formation of the decommissioning trust fund – while the plant is operating – and its use once the plant is shut down. Decommissioning financial assurance requirements which must be met over the entire life of the plant are spelled out in 10 CFR 50.75 (US, 2019). This regulation includes requirement for determining the sufficiency of the fund to provide for decommissioning at end of plant life and for biennial reporting to NRC on the result of this determination. Use of the trust fund upon shut down is governed by 10 CFR 50.82(a)(8) (US, 2019). This regulation allows initially for up to 3% of the fund to be used for decommissioning planning and 20% of the fund to be used once the licensee has submitted the PSDAR. Use of any funds above these amounts is not allowed until after the licensee has submitted to NRC a detailed site-specific cost estimate for the project (US, 2019).

Once decommissioning is complete, licensees must submit, to NRC, an application to terminate the license which must include a license termination plan at least 2 years prior to the date on which approval of termination is being sought. This submittal is defined in 10 CFR 50.82(a)(9). The radiological criteria which must be met in order for the license to be terminated are spelled out in 10 CFR 20 Subpart E (US, 2019).

US decommissioning practices

The process of decommissioning a nuclear power plant actually begins long before a decision has been made to shut the plant down. Three important activities take place while the plant is still operating;

1. The accumulation of funding sufficient to complete the decommissioning project. The plant owner sets funds aside in accordance with the requirements described above.
2. The radiological and environmental characterization of the plant. Records of plant conditions are collected throughout the operating life of the plant. How these records are organized and maintained will determine how well defined the task of decommissioning can be. Ideally, at the time of shutdown, a clear picture of the extent to which radioactive and hazardous materials are present and where they exist will be in place to guide the decommissioning effort.
3. The development of a decommissioning plan and strategy. At the time a plant shuts down, there will be many options for the path ahead. Based on what is known about available funding and plant conditions at the time of shutdown (the results of activities 1 and two above) the plant owner will then lay out the path from certification of permanent reactor defuel to termination of license. This path can involve both periods where the plant is in SAFSTOR and plans where active DECON is underway. Optimizing activities along this path is essentially a complex project management challenge. The success of this project will be determined by the skill of the project planners.

Once the radiological and environmental conditions of the plant are sufficiently characterized, the decommissioning project can be planned in earnest. As spent fuel is, by far, the most significant source of radioactivity on site, priority is placed on getting all of the fuel out of the plant and into a co-located dry storage facility – known as an Independent Spent Fuel Storage Installation (ISFSI) – before beginning active DECON of the plant. Even if the plant is to be placed in SAFSTOR for a period of time, getting all of the spent fuel into an ISFSI at an early stage will significantly reduce the risk profile of the plant and allow a number of plant systems to be taken out of service, hence reducing costs.

After spent fuel is removed from the plant's spent fuel pool and into an ISFSI, the decommissioning focus will shift to the reactor vessel internals and primary systems – steam generators (PWR), turbine/condenser (BWR), reactor coolant pumps, pressurizer (PWR), and connecting piping (ANS, 2019b). There are many options for decontaminating, segmenting, and preparing these components to be shipped offsite to existing disposal facilities which are designed and approved to accept these materials. Skilled project managers must consider both technical and business considerations in determining which options to pursue, in what order to pursue them, and whether work can be performed in parallel or must be performed in series. The results of the radiological and environmental characterization of the plant will inform this decision-making. Use of plant space, radwaste volume, worker protection, and cost must all be considered.

Reactor vessel internals have the highest radioactivity levels of anything in the plant except for the spent fuel (ANS, 2019b). Once characterized, decisions must be made about how to segment, package, and, if possible, ship these components offsite. Segments will fall into one of 4 classifications depending on level of radioactivity – Class A, B, or C low level waste or Greater than Class C waste (GTCC). Multiple options exist for packaging and disposing of Class A through C low level radioactive waste, however, there is currently not a disposal path in the US for GTCC. GTCC waste is placed into dry cask storage and stored in the ISFSI with the spent fuel. Once the GTCC has been separated out, Class A through C wastes can be packaged for disposal. In some cases, this is accomplished by placing these components back into the reactor vessel (which is typically categorized as Class A Waste) and shipping the entire vessel offsite for disposal (ANS, 2019b).

Before the reactor vessel and its internals can be segmented, accessible space must be created in the plant for the conduct of this work – including room for shielding to protect workers. This means that the strategy for addressing the reactor vessel will be affected by the strategy for decontaminating and dismantling the primary system components surrounding it. Here, as with the vessel itself, characterization is the key to success. Based on what is known, a chemical decontamination strategy can be deployed to facilitate the optimal dismantling of primary systems with a minimum volume of low-level waste generation. An effective decontamination strategy will simplify access for workers to dismantle the systems, minimize the spread of contamination, and reduce the amount of low-level waste that must be disposed of (ANS, 2019b).

While the reactor vessel internals and primary systems represent the most significant aspects of radiological decommissioning, the status and condition of the entire plant is carefully considered and factored into planning throughout the decommissioning process. For example, some support systems – such as water cleanup, ventilation, and electric power – will need to remain operational. In some cases, it will be prudent to maintain or modify existing plant systems and in other cases temporary systems will be brought in to take the place of permanent equipment that is being taken out of service.

Upcoming decommissioning work in the US

During the decade between 2020 and 2030 the US is expected to see a significant increase in the amount of active decommissioning work being conducted as a number of recently shutdown plants (see Table 2) transition from SAFSTOR into DECON and a number of currently operating plants (see Table 3) cease operations and enter decommissioning. The measures that the US industry is taking to address this increased workload are next discussed.

U.S. decommissioning marketplace evolution

After a number of nuclear power plant decommissioning projects had been completed in the US, it became apparent that the organizational skill set best suited to decommissioning a nuclear power plant was, in fact, very different from the organizational skill set

Table 3 US Plants projected^a to enter decommissioning before 2025 (NEI, 2019b).

<i>Plant</i>	<i>Location</i>	<i>Expected date to cease operations</i>
Duane Arnold	Palo IA	2020
Indian Point 1, 2, & 3	Buchanan NY	2020–2021
Beaver Valley 1&2	Shippingport PA	2021
Palisades	Covert MI	2022
Diablo Canyon 1&2	San Luis Obispo County CA	2024–2025

^aThis projection is based on shutdowns announced as of August 7, 2019. The actual list of plants that will shut-down may vary depending on electricity market conditions and future policy decisions at the State or Federal level that could affect market conditions in ways that either incentivize or dis-incentivize the continued operation of nuclear power plants.

best suited for operating one. This has led to a trend away from operating utilities “self-performing” plant decommissioning and to the rise of highly experienced and skilled decommissioning companies who specialize in managing these projects under one of three different business models. These are described as follows:

- **Contract Oversight** – responsibility for the conduct of decommissioning is placed in the hands of an expert company under contract to the utility. The utility oversees the contract and retains ownership of the facility (including fuel) as well as possession of the NRC license. The expert company’s success is determined by their ability to satisfy the terms of the contract.
- **Shared Stewardship** – The NRC license for the facility and a fixed amount of capital is transferred to an expert decommissioning company that conducts the decommissioning project. Upon termination of the NRC license, the site and the ISFSI containing the used fuel are transferred back to the utility. The expert company’s success is determined by their ability to achieve license termination on time and under budget.
- **Asset Acquisition** – An expert decommissioning company purchases the facility (including the fuel) and the license along with the decommissioning trust fund is transferred to the new owner. The expert company’s success is determined by their ability to complete the decommissioning with the resources of the existing trust fund, either move the fuel offsite or recover the costs of maintaining the ISFSI from the federal government, and recover the value of the land once the project is complete and the fuel is moved off site.

The trend away from utilities self-performing decommissioning towards business models that place the projects increasingly in the hands of decommissioning expert company is illustrated in **Table 4** which categorizes active and completed projects by business model.

Table 4 Business approach for active or completed major US decommissioning projects^a (USNIC, 2019; ANS, 2019c; Wyman, 2017).

<i>Business model</i>	<i>Plant</i>	<i>Utility</i>	<i>Expert company</i>	<i>Date plant ceased operations</i>	<i>Date decom. complete</i>
Self-perform	Rancho Seco	Sacramento Municipal Utility Dist.	NA	1989	2009
	Shoreham	Long Island Lighting Company	NA	1989	1992
	Yankee Rowe	Yankee Atomic	NA	1992	2007
	Trojan	Portland General Electric	NA	1993	2005
	Haddam Neck	Yankee Atomic	NA	1996	2008
	Maine Yankee	Yankee Atomic	NA	1996	2005
	Big Rock Point	Consumers Power	NA	1997	2007
Contract Oversight	San Onofre	Southern California Edison	Energy Solutions (plant) & Holtec (ISFSI)	2013	Ongoing

	Three Mile Island Unit 2	First Energy	Energy Solutions	1979	Ongoing

^aDoes not include plants currently in SAFSTOR (Three Mile Island 1, Kewaunee) or smaller scale reactors (Pathfinder, Ft St Vrain, and Saxton).

^bIn SAFSTOR with some DECON until 2016 when NRC license was transferred to Energy Solutions.

^cIn SAFSTOR until 2011 when NRC license was transferred to Energy Solutions.

International decommissioning

In general, the decommissioning marketplace is not as well defined outside the US. There are considerable uncertainties as to the timing and nature of decommissioning processes going forward. Also, the degree to which project funding is established through a decommissioning trust fund which was accumulated during plant operation varies (although in many cases this because the financing of the project is backed by the government). However, in one respect, the decommissioning marketplace is often better defined outside the US – in many countries centralized, off-site, interim storage capabilities exist to facilitate the removal of spent fuel from the site so that when decommissioning of the plant is complete, the land may also be released.

To date, approximately half of the completed decommissioning projects in the world have been accomplished in the United States (those listed in Table 1). However, worldwide, approximately 140 commercial power reactors have permanently shut down and either are or will be undergoing decommissioning (IAEA, 2017). There are three primary factors affecting the scope of the global decommissioning marketplace.

1. National decisions to phase out nuclear power, such as those taken in Germany and Taiwan (Reuters, 2019; World Nuclear News, 2019).
2. Aging of the global nuclear fleet (over 50% of the world's 448 operating nuclear power reactors are more than 30 years old) (IAEA, 2017).
3. The extent to which Japan may, or may not, be successful in regaining sufficient public confidence to restart its reactors in the wake of the Fukushima accident (Mizokami and Rempe, 2021) All of Japan's 57 operating reactors were shutdown following the accident. At the date of this publication, only 9 of these have gained approval to restart. Twenty-four reactors have entered decommissioning or are set to be decommissioned, and the fate of the remaining 24 has yet to be decided (Japan Electric Power Information Center, Inc., 2019).

As decommissioning becomes more common around the world, a number of challenges will be encountered. Legal and regulatory frameworks are incomplete in some countries. Funding uncertainties are common and waste disposal paths are often unknown. Finally, the global workforce will be stretched to provide skilled and experienced labor.

Summary

U.S. nuclear plant owners have safely completed the decommissioning of 10 commercial nuclear power plants. This has been accomplished through careful advance planning – utilizing the resources of trust funds established during plant operations and guided by a well-established regulatory framework. The pace of decommissioning in the U.S. is accelerating with 15 reactors at 11 sites currently undergoing decommissioning and 9 reactors at 5 sites poised to enter decommissioning between 2020 and 2025.

This experience has led to a refinement in techniques for decontaminating and dismantling nuclear plants as well as for the management of spent fuel and low-level radioactive waste. The deployment of innovative new business models is building on the lessons learned from past experience to enable the U.S. nuclear industry to improve efficiency as demand for decommissioning services increases. Although international experience varies, this experience is also informing global efforts to meet an expected increase in decommissioning activity worldwide.

Introduction	247
Decommissioning progress	247
Summary	250
References	250

Introduction

On May 7, 2013, after 39 years of operation, the Kewaunee nuclear power station ([Fig. 1](#)), which includes a single unit Westinghouse pressurized water reactor, permanently ceased operations. On May 14, 2013 Dominion Energy (Dominion), the plant owner, certified that all fuel had been permanently removed from the reactor vessel and placed in the spent fuel pool ([Dominion Energy Kewaunee, Inc., 2013a](#)). At that time, the plant owner/operator, Dominion Energy Kewaunee Inc. announced that it intended to place the plant in SAFSTOR. [McCullum \(2021a\)](#) describes the SAFSTOR option. Kewaunee is one example of plants at which this option is being pursued.

Decommissioning progress

In February of 2013, Dominion completed a Post Shutdown Activities Report (PSDAR) ([Dominion Energy Kewaunee, Inc., 2013b](#)). As described in [McCullum \(2021a\)](#), this document laid out a schedule for SAFSTOR and the eventual decommissioning of the plant and included a cost estimate. The schedule called for all SAFSTOR preparations to be completed by 2020 and for the plant to then enter a period of dormancy with all fuel in dry storage until 2050. Dominion estimated that spent fuel would be removed from the site in 2050 (an uncertain date given the US Department of Energy's long history of delay in fulfilling its contractual obligations to remove used fuel from commercial reactor sites) and then the site would remain dormant until 2067.

According to Dominion's plan, workers and equipment will return to the site in 2067 to begin dismantlement of plant structures, removal of plant systems, and site decontamination. This process is expected to be completed by 2072. Then, in 2073, site restoration work will restore the site to a greenfield condition. During this time the natural process of radioactive decay and the interest earned on the decommissioning trust fund (not to mention potential technological advances that occur over that time) will make

Fig. 1 Kewaunee Nuclear Station in 2013 (located in Carlton, Wisconsin). Wald ML (2013) As price of nuclear energy drops, a Wisconsin plant is shut. *New York Times*, 7 May 2013.

their job easier. There will be less low-level radioactive waste that will need to be shipped off site and, based on conservative financial projections, the trust fund will grow to be more than adequate to pay the \$920 million cost that Dominion estimates for this entire process. In 2013 the US Nuclear Regulatory Commission reviewed Dominion's cash flow analysis and found that the existing trust fund would be adequate to cover all decommissioning, spent fuel management, and site restoration costs.

Of course, a lot can change over 60 years. Dominion's estimated schedule takes a purposefully long view in order to demonstrate that it is, in fact, capable of meeting NRC's requirements for exiting SAFSTOR and completing the decommissioning of the plant—up to license termination—within the allowable 60 years. At any point in the future, Dominion may decide to accelerate the project if it proves prudent to do so. In fact, the plant is already moving into dormancy ahead of schedule. All fuel was moved into dry storage in July of 2017, 3 years and 5 months earlier than originally planned.

In 2019, the Kewaunee site still looks pretty much the same on the outside—with most major structures still standing. But inside things could not be more different. A skeleton crew carefully watches over physical, environmental, and radiological conditions in the dormant facility with only a minimal amount of equipment operating to maintain the condition of the plant in anticipation of the arrival of its destruction decades in the future. Conditions in the plant are adjusted to prevent any undue degradation of plant structures that would complicate the task of future destruction workers when they arrive and to assure that no hazardous materials are released beyond the facility fences. In some cases, where it is economical to do so, existing plant equipment has been modified to provide ventilation flow, electricity, potable water, and fire protection in those areas where it is still needed. In other cases, where continued reliance on existing systems would be inefficient, these systems have been taken out of service and replaced with smaller more economical new systems to provide necessary utility services. The plants control room (Fig. 2) is largely a relic, albeit a neat and tidy one, with all but a few panels—those still linked to the existing systems that have been retained—de-energized and long inactive.

Inside Kewaunee's dormant rooms, there is a notable scarcity of radiation zone postings that would typically be found at many locations in an operating plant. The radiation protection offices, where teams of health physicists used to be busy around the clock assuring that workers were protected and that no contamination was taken offsite, are dark and empty. Their sophisticated monitoring and survey equipment is long gone. Before entering dormancy, plant workers removed readily accessible radioactive contamination. These materials were shipped offsite to low level waste disposal facilities in a manner similar to what operating plants do on a routine basis. The bulk of the radioactive materials remaining at the site are entrained inside the still-standing structures and systems along with the spent fuel on the ISFSI site. It is a testament to the meticulous efforts of those health physicists during plant operation that, upon plant shutdown, this was not a difficult task. For example, after the spent fuel pool was drained, it was simply hosed down for decontamination with a negligible amount of waste generation. In 2019, one can stand directly over the empty pool (Fig. 3), look down into the now dry expanse through which passed every single spent fuel assembly—containing the radioactive byproducts of nearly four decades of splitting uranium atoms—and receive no radiation exposure.

Fig. 2 Kewaunee Nuclear Station control room in 2019. Only few panels are functioning (*lights on*). McCullum R (2019) Notes and photos taken from tour of Kewaunee site, 25 September 2019.

Fig. 3 Kewaunee Nuclear Station spent fuel pool in 2019; without fuel and water. McCullum R (2019) Notes and photos taken from tour of Kewaunee site, 25 September 2019.

Fig. 4 Kewaunee Nuclear Station Independent Spent Fuel Storage Installation (ISFSI) in 2019. McCullum R (2019) Notes and photos taken from tour of Kewaunee site, 25 September 2019.

The fission products contained in the spent fuel assemblies remain stored in dry casks (Fig. 4) on a concrete pad just north of the plant awaiting the anticipated 2050 arrival of the US Department of Energy (DOE) to transport them off to final disposal. The concrete pad and the dry cask storage systems that sit on it are fenced off from the rest of the plant, inside a unique security perimeter, in an Independent Spent Fuel Storage Installation (ISFSI) that is regulated under a separate NRC license in accordance with 10 CFR Part 72. The separation of the ISFSI from the rest of the plant prevents the continued presence of spent fuel on the site from

interfering with the decommissioning of the plant. These storage systems also provide a high degree of safety protection for the spent fuel without reliance on plant systems. They have been designed and tested to withstand severe events such as earthquakes, floods, tornados, airplane crashes, and explosive fires. Even if the DOE does not remove the spent fuel in 2050—which could happen if political controversy continues to delay the US spent fuel disposal program—the active decommissioning of the plant can still proceed on schedule beginning in 2067. It is, in fact, quite common for plant decommissioning to be completed¹ while the separate ISFSI remains in place. This is illustrated by the Maine Yankee example detailed in [McCullum \(2021b\)](#).

Summary

Dominion Energy permanently ceased operations of its Kewaunee Nuclear Power Station in 2013. The plant was immediately placed in SAFSTOR. Although the fundamental concept of SAFSTOR is to wait on decommissioning until some future time after levels of radioactivity have decayed and decommissioning and trust fund resources have grown through accumulated interest, several activities have been conducted to assure that industrial and radiological safety is maintained in all areas of the plant throughout the SAFSTOR period. Accessible areas of the plant have been decontaminated, plant systems have been modified, and all spent fuel has been placed in an onsite ISFSI. Dominion anticipates completing the NRC required decommissioning process in 2072 and begin restoring the site to a greenfield condition in 2073. The total cost of this project at completion is expected to be \$920 million. ([Dominion Energy Kewaunee, Inc., 2013b](#)).

¹The decommissioning process is considered complete when all plant structures and systems have been decommissioned such that the NRC license can be terminated. Spent fuel may remain on the site after this point in a separately licensed Independent Spent Fuel Storage Installation (ISFSI). In cases where an ISFSI remains on site, the land cannot be released for other purposes. So, in these cases, while the decommissioning is considered complete from a technical and regulatory point of view, from a public perception point of view it is not considered complete due to the continued presence of radioactive material on the sites.

Introduction

On August 6, 1997, amidst an extended shutdown for repairs, the Maine Yankee Atomic Power Company Board (the Board) voted to decommission the Maine Yankee Nuclear Power Plant or Maine Yankee ([Fig. 1](#)), which included a single unit Combustion Engineering pressurized water reactor, after 25 years of operation. The next day, the Board submitted to the US Nuclear Regulatory Commission (NRC), a certification of permanently ceasing power generation operations and a certification of permanent removal of fuel from the reactor. In making this decision, the Board determined that prompt dismantlement was the most economically advantageous approach for electricity ratepayers ([EPRI, 2005](#)). Therefore, Maine Yankee went immediately into DECON upon termination of operations.

[McCullum \(2021\)](#) outlines the steps in the DECON process until the point at which the technical and regulatory definition of complete is met, even though spent fuel may remain on the site in a separately licensed Independent Spent Fuel Storage Installation (ISFSI). Maine Yankee is one example of this situation.

Decommissioning progress

Decommissioning planning activities commenced in 1996, even as the Board was still contemplating the decision to cease operations. These activities included: drafting of the Post Shutdown Activities Report (PSDAR) ([Maine Yankee Atomic Power Co, 1997](#)); the advance preparation of a number of exemption requests that would need to be submitted to the NRC to transition from operating plant regulatory requirements to the more limited set of regulations that would remain applicable to a shutdown plant site;

Fig. 1 Maine Yankee Nuclear Plant in 1998 (located in Wiscasset, Maine) ([Bangor Daily News, 2013](#)).

estimating plant decommissioning costs for all available options; evaluating decommissioning approaches; and planning necessary interactions with the community surrounding the plant.

Between August of 1997 and July of 1998, Maine Yankee entered into a transition period in which decommissioning plans were finalized and a Decommissioning Operations Contractor (DOC) was selected to perform the work. In August of 1998, Stone and Webster Engineering Corporation (SWEC) was awarded a turnkey, fixed-priced DOC contract. However, this arrangement proved problematic to implement. By July of 2000, the DOC contract had been terminated, and the Maine Yankee Atomic Power Company took over management of the work to self-perform the decommissioning (EPRI, 2005).

One of the most important decisions that needed to be made early in the decommissioning process was the selection of a spent fuel management strategy. When Maine Yankee ceased operations in 1998, the nuclear industry was just beginning to come to terms with the US Department of Energy's (DOE) default on its statutory and contractual obligation to begin removal of spent fuel from reactor sites in January of 1998. With the Yucca Mountain Repository Project significantly delayed, there was considerable uncertainty as to when DOE would arrive at the Maine Yankee site to begin removing fuel. Maine Yankee had not yet implemented dry cask storage in response to spent fuel pool capacity limitations as had a number of other operating plants because available space for future reactor offloads still remained at this point.

The Board initially chose to adopt a spent fuel island approach in which spent fuel pool related systems would be isolated from the rest of the plant and operated in a self-contained manner until DOE would arrive to remove the spent fuel. Obviously, this would limit the extent to which the plant could be dismantled. A business case conducted early in the decommissioning process indicated that, assuming DOE did not remove the spent fuel prior to 2019, it would be economically advantageous to deploy dry cask storage. Between 2000 and 2002, an Independent Spent Fuel Storage Installation (ISFSI) was constructed and the transfer of all spent fuel to the ISFSI pad was completed by February 2004 (EPRI, 2005).

In parallel with the spent fuel decision-making, three early projects were undertaken to prepare the plant for dismantling – asbestos abatement, radioactive hot spot reduction, and reactor coolant system decontamination. As was the case with most reactors built in the 1970s, asbestos was widely used at Maine Yankee for insulation, fire protection, and in various paints and tiles. An estimated 28,500 cubic feet of asbestos would be removed from the plant (EPRI, 2005). One third of this material was radioactively contaminated and required disposition at a licensed low-level radioactive waste disposal site. The asbestos remediation project began in March of 1998 and was completed in December of 1998. Radioactive hot spot reduction¹ and reactor coolant system decontamination activities were conducted to reduce the radioactive source term in the plant as a worker protection measure. Radiation surveys identified hot spots so that affected equipment could be carefully cut out of affected systems. This project is estimated to have reduced total project radiation exposure by approximately 150 person-rem (EPRI, 2005). A similar dose reduction was achieved via a through chemical decontamination of the reactor coolant system. All source term reduction activities were completed by May of 1999 (EPRI, 2005).

By December 1998, Maine Yankee had reached a “cold and dark” state where liquid containing systems had been drained and power to electrical components had been removed (EPRI, 2005). From this point, major component dismantlement could begin. Throughout 1999, major components such as reactor coolant pumps were removed and shipped off site for disposal in licensed

Fig. 2 Maine Yankee Reactor Vessel ready for shipment to Barnwell LLW site in 2003 (EPRI, 2005).

¹Radioactive hot spots are areas where, in accordance with 10 CFR Part 20, special worker protection measures are required.

low-level radioactive waste facilities. The most significant work internal to the plant was the segmentation of reactor vessel internals (the most highly radioactive components other than the spent fuel). This activity, which commenced in November 2000, was performed in the flooded refueling cavity using abrasive water jet and mechanical cutting techniques (EPRI, 2005). The segmented internals were separated into three categories of waste – low level waste that would be shipped offsite inside the reactor vessel (Fig. 2), low level waste that would be shipped offsite in separate casks, and Greater than Class C (GTCC) waste – a category designated by NRC as between low and high level requiring geologic disposal. About 10% of the materials resulting from the complete dismantling of the nuclear plant were classified as GTCC (See McCullum, 2021). These materials were placed in the same type of dry casks as the spent fuel and placed on the ISFSI pad along with the fuel in April of 2003. The reactor vessel was shipped offsite in August of 2003 (Fig. 2).

With radioactive components removed, focus shifted to demolition of the concrete structures on site. An approach to demolition using explosives was established, tested and used to bring down the turbine building, the 330-ton polar crane inside the containment building, and finally, in September of 2004, the containment building itself (Fig. 3).

Throughout the project, stakeholder input was a significant factor in all decision-making. A Community Advisory Panel was formed in 1997 and functioned throughout the project as a conduit for public involvement in the decommissioning process. Having an informed public was vital to successfully navigating both the State permitting and federal regulatory processes. A total of three federal agencies (NRC, Environmental Protection Agency, and Federal Energy Regulatory Commission) and seven state agencies had authority over various aspects of the process. In a number of these areas, public interest groups intervened in regulatory matters.

Stakeholder input was probably most valuable in reaching decisions about the final end state to which the Maine Yankee site would be restored. By 2019, aside from the ISFSI and a remaining active switchyard, a visitor to the site would find it difficult to believe that a commercial nuclear reactor had stood on the green field along the banks of the Back River (Fig. 4). Maine Yankee's NRC license was terminated in October 2005, all State agency commitments were also met. The site, except the ISFSI, is now ready to be released for other purposes. The total cost of the project to that point was approximately \$500 million (EPRI, 2005).

Summary

The Maine Yankee Atomic Power Company permanently ceased operations of its Maine Yankee Power Station in 1997. The plant was immediately entered DECON. As one of the earlier commercial reactor decommissioning projects in the U.S., Maine Yankee's experience would become the source of many lessons learned that would be applied over the next two decades at numerous other commercial reactors that would enter decommissioning over the next two decades. Although the project would have to make a number of course corrections in its early stages – refining the overall management and spent fuel strategies – it ultimately became a success story. DECON was completed, in accordance with NRC regulations in 2005 at a total cost of approximately \$500 million (EPRI, 2005).

Glossary

Fuel cycle front end The term given to the range of nuclear fuel cycle activities necessary to prepare nuclear fuel for utilization in nuclear reactors.

Fuel cycle back end The term given to the range of nuclear fuel cycle activities employed to handle and treat used nuclear fuel upon discharge utilization in nuclear reactors.

Nuclear fuel A mixture of elements, including fissile isotopes, used to establish a sustainable fission chain-reaction and release energy in a nuclear reactor. The form can be solid in any of a number of chemical compounds or metal alloys, or liquid with fuel constituents in solution such as a molten salt or an aqueous solution. Still other forms have been proposed and considered.

Nuclear fuel cycle (or simply “fuel cycle” in this context) The lifecycle of nuclear fuel from extraction of a natural resource, such as uranium or thorium, through mineral processing concentration, sale on the market, isotopic enrichment, conversion to desired chemical compound, fabrication into a usable form, loading into the reactor core to generate energy, recovery and, optionally, recycle of re-usable constituents (if deployed), treatment of waste constituents for disposal, and disposal. In a narrower context, engineers might also use the term “fuel cycle” when referring to the planning and optimizing of fuel loading and management in the core of an operating reactor.

Introduction

Nuclear fuel is a mixture of elements and isotopes used to establish a fission chain reaction and release fission energy in a nuclear reactor. The supply chain for light water reactor (LWR) fuel is mature and configured to provide fuel for nuclear reactors at the lowest possible cost. Some advanced reactor designs, with prospect for improved safety and sustainability, reduced waste and improved economics, call for different fuel cycle strategies and for different fuel forms and designs. Whether those reactor systems are successfully deployed in energy markets will depend in part on whether and how quickly the fuel supply chains for those systems mature to sufficient economic efficiency. Deployment requirements for research and test reactors are different; however, motivations for new fuel designs for research and test reactors include reduction in operating costs, improved operating reliability, and reduction of ^{235}U content.

Purpose of this chapter

This chapter introduces the Fuel Cycle Front End: Mining through Utilization Section of this *Encyclopedia*, providing context for the chapters that follow. It presents an overview of the nuclear fuel cycle and describes design considerations important to fuel technology.

Fig. 1 Illustration of the light water reactor nuclear fuel cycle. All the activities prior to power generation (fuel utilization) are considered the front end of the fuel cycle, while those after power generation, including activities that recycle fissile material back into the front end, are considered the back of the fuel cycle. Courtesy World Nuclear Association.

Overview of the nuclear fuel cycle

The industry that provides nuclear fuel is considerably more complex than that for fossil fuel. Unique aspects of the nuclear fuel industry include the need to convert uranium and uranium oxides to uranium fluoride needed for enriching the natural uranium with the fissile isotope ^{235}U and then converting the enriched uranium fluoride gas to a solid metallic uranium or a uranium compound, the removal of hafnium (a neutron poison with chemical characteristics similar to zirconium) from zirconium (the metal used in LWR fuel cladding), and the rigor applied to quality controls.

The fuel cycle for LWRs is considerably more developed than those for other reactor types, due to the size of the LWR fuel market. Variations from the LWR fuel cycle for application to other reactor types are also indicated. The main elements of the nuclear fuel cycle are depicted in Fig. 1 and described below.

Mining and milling

Uranium is mined in a manner similar to other mineral resources using hard-rock techniques, such as underground mining, surface mining, and open pit mining. See Hore-Lacy (2021) for an overview of uranium mining practices. In-situ leaching or in-situ recovery is also used where economically warranted. Uranium ore is crushed and ground to reduce particle size, increasing the specific surface area of the rock to improve the kinetics of dissolution into acidic or alkaline solutions for concentration of the uranium into “yellowcake,” or U_3O_8 . Uranium milling produces a considerable volume of waste products, or tailings, per unit of yellowcake. Remediation of tailings, not always addressed in the past but now included in modern milling operations, ensures that abandoned tailings piles don’t become sources of wind-blown radioactive dust particles or ground-water contamination.

Although Thorium is considerably more plentiful than uranium, uses of thorium are not currently significant enough to motivate commercial-scale production of thorium. Development and deployment of nuclear power using a thorium-based fuel cycle could change that.

Conversion

Yellowcake is converted to UF_6 , primarily because UF_6 can be shipped at ambient temperatures as a solid but can be heated to relatively low temperature (to or above 57°C) to form UF_6 gas, which is suitable for enrichment (Hogan, 2021). Conversion to UF_6 can be accomplished using a wet process, beginning with dissolution in nitric acid followed by solvent extraction to purify the uranium oxide and series of steps that fluorinate the oxide. Alternatively, UF_6 can be formed from U_3O_8 in a dry process using a series of reactions with hydrogen, HF, and fluorine (Benedict et al., 1981, pp. 272–274).

Enrichment

Natural uranium is comprised of, by mass, 0.72% ^{235}U , 99.27% ^{238}U , and trace amounts of ^{234}U . With the exception of heavy-water-moderated reactors (HWRs), such as the CANDU reactor (Nichita, 2021), and graphite-moderated reactors, such as the Magnox reactors in the United Kingdom, most reactor types require uranium enriched in the ^{235}U isotope to 3% or greater to achieve criticality and enable reactor operation for a practical length of time. Although the atomic masses of ^{235}U and ^{238}U are very similar, the 1.3% mass difference is sufficient to allow segregation of uranium by mass to produce a product that is enriched in ^{235}U and a tailings by-product that is depleted in ^{235}U (see Hogan, 2021).

Processes used to enrich uranium include centrifugal separation and gaseous diffusion through a membrane. Each process requires a large number of stages in succession, because the mass difference between ^{235}U and ^{238}U is small. Laser enrichment processes, which operate on uranium in atomic or molecular form, continue in development but have not yet been commercially

deployed. The processes offer prospect for much greater separation efficiency with associated improvements in capital cost, tailings assay, and required energy input.

The energy invested in uranium enrichment is measured in Separative Work Units (SWU), which is a complex derivation reflecting energy input per amount of uranium input, degree of enrichment of ^{235}U in the product stream, and the degree of depletion of ^{235}U in the tailings stream. The Separative Work Units of separating a mass F of feed with ^{235}U enrichment x_f into a mass P of product with ^{235}U enrichment x_p and tailings of mass T with ^{235}U enrichment x_t , can be expressed as the following (U.S. E.I.A., 2020; Benedict et al., 1981, p. 669):

$$\text{SWU} = TV(x_t) + PV(x_p) - FV(x_f) \quad (1)$$

$$V(x) = (1 - 2x) \ln \left(\frac{1 - x}{x} \right) \quad (2)$$

Note that the units for SWU will be the same as the units used for the values of F , P , and T , which can be expressed as kg, moles, or atom fraction, provided the values for enrichment (x_f , x_p , and x_t) are expressed on the same basis (weight fraction, mole fraction, or atom fraction).

Deconversion

After enrichment, the enriched uranium product is chemically converted into the form best suited for the desired fuel, usually UO_2 powder given the large market for UO_2 fuel in LWRs. Conversion of UF_6 to UO_2 can be accomplished using a wet process, through reactions with water and ammonium (or ammonium carbonate) followed by filtering and heating in a reducing environment. The alternative dry process heats UF_6 to the gaseous state, for contact with steam and then H_2 -rich steam to produce UO_2 . The dry process has some advantages over the wet process, producing less waste and keeping the uranium in a solid form that can be easier to contain than a uranium-bearing solution. For processes that subsequently sinter UO_2 powder into pellets, the powder characteristics are very important, so process steps are often adjusted to result in powder that leads to the best fuel quality. Some fuel production processes, such as those used to make tri-structural isotropic (TRISO) fuel for high temperature gas-cooled or molten-salt-cooled reactors, use sol-gel precipitation processes to produce highly regular ceramic particle shapes of UO_2 or uranium oxycarbide (UCO) suitable for coating (Helmreich and Hunn, 2021). Production of other chemical and physical forms of the uranium material, such as uranium metal, uranium nitride or carbide, or uranium salt, is also possible, though UO_2 is the only form in industrially significant use today.

Fuel fabrication

Fuel fabrication includes all the steps needed to process uranium into form necessary for a specific reactor design. Ceramic powders such as UO_2 , $(\text{U,Pu})\text{O}_2$, UN, and $(\text{U,Pu})\text{N}$ are compressed into pellets for use in LWRs, HWRs, or fast reactors (see Kato, 2021). Those pellets are then loaded into cladding tubes, made of zirconium alloys or stainless-steel alloy to form fuel rods that are assembled into square (for most designs) fuel bundles and assemblies. However, TRISO particle fuel for high-temperature gas reactors or molten-salt-cooled reactors is fabricated in very different manner, which coats individual powder particles which are then consolidated into a graphite matrix shaped as cylindrical compacts or spherical “pebbles,” as described by Helmreich and Hunn (2021).

Metallic uranium might be alloyed with molybdenum or zirconium and cast into ingots or fuel slugs suitable for production of research reactor fuel or fast reactor fuel. Research reactor fuel is commonly encapsulated in cladding to form plates which are then assembled into fuel elements (Cole et al., 2021a,b). Metal fast reactor fuel is placed into a cylindrical cladding tube (Porter and Crawford, 2021), usually with metallic sodium filling the annular gap between the fuel and the cladding, to form fuel rods that are assembled into hexagonal fuel assemblies (or subassemblies, depending on terminology).

Nuclear fuel is produced to very exacting quality requirements, which makes nuclear fuel production very specialized. Descriptions of the more common fuel designs in use or under consideration today appear later in this chapter.

Service

Fuel cycle steps in the progression up to fuel service, or use, are considered to be the front end of the fuel cycle. Nuclear fuel is placed into service when it is loaded into a reactor core and the core is made critical. The great majority of the reactors in the world are used for generating power, but there are other reactors intended to provide neutrons for irradiation testing or production of isotopes. The in-service lifetimes of solid nuclear fuel are usually limited by the degradation of material properties that reduces the ability of the fuel to perform its safety and design functions. In some specialized reactors with very high power density or reactors proposed to operate with molten salt fuel, the fuel lifetime will be limited more by depletion of fissile isotopes than by reduction in fuel integrity. At the end of the fuel's lifetime, fuel assemblies (or fuel salts, in the case of molten-salt-fueled reactors) are removed from the reactor and replaced with fresh fuel.

Used fuel management and storage

The subsequent steps in the fuel cycle progression after use, with used nuclear fuel, are considered the back end of the fuel cycle, as described by Glatz (2020) and Kessler (2021). Upon discharge, used fuel assemblies are usually cooled to allow fission products to decay to lower heat generation rates. This cooling often is carried out in fuel pools, for water-cooled reactors, or in other facilities

configured for efficient removal of decay heat. After decay heat output is reduced sufficiently, used fuel can be removed from cooling locations and placed into dry storage to await final disposition. Even in post-service storage, fuel integrity is important for continued containment of radionuclides in the fuel. Provisions are made for storage and containment of failed or breached fuel, and their storage requires additional attention.

Reprocessing and/or disposal

The final disposition of used nuclear fuel varies by country. For nations that implement or otherwise allow fuel recycling, many options are available (Shwageraus, 2021; Wigeland et al., 2021). Some nations utilize large fuel reprocessing facilities in which used fuel is dissolved into aqueous solution and plutonium is (or all transuranic elements are) separated and consolidated for reuse in new fresh fuel. In those facilities, fission products and the higher actinides are consolidated into waste forms intended for geologic disposal. In other nations, economics or policy decisions discourage commercial investment in used nuclear fuel reprocessing facilities, so the reference plan for disposition of used fuel is direct disposal in a geologic repository. Regardless of the disposition strategy, the radiotoxicity, chemical toxicity, and safeguards associated with used nuclear fuel brings a set of technological challenges unlike those experienced in most other industries. Glatz (2020) and Kessler (2021) describe the various options being considered for the back-end of the fuel cycle, and the specific technologies are addressed by other authors (Senentz, 2021; Marin, 2021; Boullisand Chabert, 2021; Miguiditchian, 2021; Gonzales, 2020; Grambow, 2021; Ewingand Park, 2021).

Fuel design

As a component of a nuclear reactor, nuclear fuel is key to establishing the fission chain reaction for generating nuclear energy and for ensuring safe containment of the fission products. Many configurations of nuclear fuel might be used successfully, but those used or considered today reflect experience gained from the earliest developments of nuclear energy. Solid fuel designs with optimal surface-to-volume ratios are preferred for most reactor technologies. However, technological limitations with solid fuel designs motivated reactor types that use homogeneous liquid forms of nuclear fuel, and molten salt fuels are a favored liquid form due to the desirable thermal and chemical properties of salt compounds. Whereas all solid fuel forms in use are encapsulated in some manner to provide a first barrier to contain fission and activation products (i.e., encased in cladding tubes or in deposited layers), for liquid fuel reactors the analogous first barrier is the reactor vessel and primary coolant loop.

Evolution of nuclear fuel technology has been driven by economics of nuclear plant operation, to (1) decrease plant operating cost by increasing fuel utilization, or (2) increase revenue by increasing power generation.

1. The economics of nuclear reactor operation depends in part on efficient utilization of the nuclear fuel. For example, in the United States for the years 2010–17, nuclear fuel cost comprised 18–21% of total operating cost of commercial LWRs, even as total operating costs have decreased (see Nuclear Energy Institute, 2018). As reactor fuel cycles call for increasing fissile enrichment to allow more energy generation per unit weight of fuel, the proportion of fuel cycle-related cost will increase. However, that additional cost is compensated by increased fuel utilization (fuel efficiency) if more energy, or more fissions, can be obtained from a given amount of fuel before the fuel must be replaced. Fuel utilization is typically limited by one or both of two things: in-service degradation of the fuel components that reduces the reliability of the fuel to contain radionuclides and the reduction of the reactivity value of the fuel as the fissile isotopes are depleted and the fission products accumulate. So, much of the development of nuclear fuel technology seeks to increase fuel utilization by decreasing and managing rates of fuel component degradation and by increasing the concentration of fissile material in the fuel.
2. Nuclear reactors are designed for efficient energy production operate at temperatures as high as the components and structures will allow. Even when reactor operating temperatures are not increased, changes in plant operation can challenge fuel designs and fuel reliability. Changes to operation of existing reactor include plant power uprates (allowing the plant to generate more power than originally designed) and increases in operating cycle length (the length of time that plant operates between fuel reloads), which can expose fuel to greater flow-induced vibrations, greater corrosion, and greater radiation-induced degradation. LWR power uprates include higher average power densities in the cores and higher coolant flow rates to safely remove the increased power. Because efficiencies of energy conversion systems are improved at higher coolant temperatures, most of the advanced nuclear reactor technologies under development feature higher coolant outlet temperatures than LWRs (Stanculescu, 2021). For a given reactor type, increases in fuel operating temperatures can increase rates of degradation and increases in coolant flow rates (which might be necessary for higher power density) can increase flow-induced vibrations that cause fretting wear on fuel components.

Fuel functional and safety requirements and fuel qualification

Fuel systems must fulfill certain functions, some of which ensure the safety of the nuclear reactor system and some of which are necessary for the nuclear reactor to operate efficiently.

Specific requirements are determined for specific nuclear reactor designs, but in general, the functional and safety requirements for solid fuel systems reflect the following:

1. The fuel system must position the fissile material in a stable and predictable manner to allow a controlled fission reaction.
2. The fuel system must allow effective transfer of nuclear fission heat and radioactive decay heat from the fuel to the coolant (heat transfer medium).
3. The fuel system must provide containment of radionuclides (fuel and fission products) for operational convenience and as a first barrier for safety. For most solid fuel systems this containment includes structural containment as well as chemical containment (i.e., some containment contribution provided by the chemical form of the fuel and fission products). In liquid fuel systems (such as molten salt) this containment is provided by the reactor vessel and the primary coolant system.
4. The fuel system must provide or allow a practical means of loading fresh fuel into the core and removing and managing used fuel. For solid fuel this can be accomplished through suitable design of the fuel assembly structures and the equipment used for fuel loading and unloading, but for liquid fuel this is accomplished primarily online by fuel processing systems.
5. The fuel must not compromise the ability of other reactor components to fulfill their safety functions; for example, fuel components must not interfere with the function of reactor control systems (e.g., in-core control rod motion), must not impair the performance of heat removal systems, and must not adversely impact other radionuclide containment barriers such as the primary system coolant boundary.

As with other nuclear reactor components, fuel designs are typically *qualified* for their purpose. Although what is needed to qualify a fuel design is not well documented, *fuel design qualification generally demonstrates, through a combination of testing and analysis, that a fuel design as-specified will perform its design-basis functions under design-basis conditions*. Other aspects of fuel qualification, such as qualification of the fuel production process or fuel handling procedures in a reactor plant, are intended to demonstrate that product and process variability are sufficiently controlled by the prescribed quality assurance regimen.

Qualification of new fuel designs is analogous to those applied to mechanical and electrical components to be used in a nuclear reactor (such as pumps, valves, circuit breakers, and switchgear): as-specified fuel systems and designs are demonstrated through analysis and testing to perform their design-basis functions.¹ The definition of the design basis includes expected fuel operating conditions: fuel, cladding, and coolant temperatures; fission power density in the fuel; rates of power and temperature change; and coolant conditions (such as flow rate and chemistry). The qualification case provides assessment of prior experience and testing and comparison of current design with previous designs. It will also include analysis of expected fuel phenomena and the comparison of those phenomena against limits (e.g., maximum fuel cladding strain or temperature margin to melting temperature). Confidence in fuel designs is typically reached with compilation of fuel material properties and sufficient experience to identify and quantify the degradation of fuel component properties and behavior that accompanies fuel use in service. If the understanding of fuel phenomena is not sufficiently established to allow confident prediction using modeling and simulation, then prior operating experience and testing is additionally important to demonstrate expected fuel reliability and margin to failure.

For a new fuel design, gathering properties and performance information can require 20 or more years, given the time needed to evaluate and demonstrate fuel behavior during in-service residence times of several years; e.g., Crawford et al. (2007). This development and qualification time varies with the maturity of the design and its similarity to other designs. The long duration and considerable investment needed to develop and qualify new fuel designs discourages introduction of innovative designs into operating, or even new, nuclear reactors. Initiatives within nuclear technology development centers, such as US national laboratories, seek to improve the innovation timeline by reducing the time and investment needed to gather the information and experience necessary to qualify a new fuel design and by establishing modeling and simulation tools sufficiently validated to allow accurate fuel behavior prediction with less test data (Terrani et al., 2020). The development of new testing techniques and validation of predictive models are underway (Tonks et al., 2017; Beausoleil II et al., 2020).

Fuel designs

The specific design objectives and optimization challenges for each reactor design or concept have motivated specific fuel design features. This is true of molten salt compositions proposed for different molten salt reactor (MSR) concepts, for example, with chloride salts preferred for some fast-spectrum systems and fluoride salts preferred for thermal-spectrum systems (Gakhar et al., 2021). But the variety of fuel design choices is particularly evident in solid fuel systems. For solid-fueled reactors, the fuel design is determined through optimization of reactor power density (which typically is preferred to be as high as possible to reduce reactor size and cost), heat removal and temperature margins needed to ensure the fuel performs its design-basis functions, and fuel production and handling cost. Heat removal generally drives designs with higher specific surface area, so rod-shaped fuel is most common, as with LWRs and most fast reactor designs, and thin plate-shaped fuel is used in most research reactors. Objectives to provide extremely robust and resilient containment of fission products has led to the TRISO particle fuel design that places the fuel material in encapsulated spheres that are then embedded in graphite spheres (or pebbles) or graphite cylindrical compacts (Electric Power Research Institute, 2019; Helmreich and Hunn, 2021).

¹For LWR component qualification in the United States, the criteria are provided in accordance with US Nuclear Regulatory Commission (NRC) *Standard Review Plan for Licensing of Light Water Reactors*, (USNRC, NUREG-0800).

Table 1 Key properties for oxide, metal, and nitride fuels for fast reactor application.

	Mixed oxide (U, Pu)O ₂	Metal fuel U-Pu-Zr	Mixed nitride (U, Pu)N
Composition	(U _{0.8} Pu _{0.2})O ₂	U-19Pu-10Zr	(U _{0.8} Pu _{0.2})N

Fuel compositions

Compositions used or proposed for many fuel systems are briefly described here. Values of key properties of different solid fuel compositions are included in **Table 1** (Arai, 2012), illustrating some of the characteristic trade-offs that must be considered when selecting a fuel type for a reactor application. Molten salt fuel compositions are introduced in Gakhar (2021).

LWR fuel: UO₂ is the most common, with ²³⁵U enrichment usually ranging from 3% to 5%. Recent developments call for fuel enrichments greater than 5% ²³⁵U, to allow longer reactor operating cycles or to compensate for design features that increase tolerance to reactor accident conditions (e.g., use of Fe-based cladding rather than Zr-based cladding). Mixed oxide fuel, or MOX, (U,Pu)O₂ is also used in countries where recovery and recycle of plutonium into reactor fuel is allowed and implemented. The design and fabrication of oxide fuels are described by Kato (2021), the irradiation performance of LWR fuel are described by Cantonwine (2020) and the properties of ceramic fuels are described by Pastore and Toptan (2021).

Research reactor fuel: Research reactors present a different set of needs, and although those reactors operate at less challenging (i.e., lower) temperatures than reactors intended for efficient power generation, research reactor fuel technology is challenged by international objectives to reduce fuel uranium enrichment to less than 20% ²³⁵U and to reduce fuel production cost. Research reactors for many years have been fueled with fuel plates comprised of uranium aluminide particles (UAl₂, UAl₃, and UAl₄) dispersed in an aluminum matrix, with ²³⁵U enrichments varied as needed to meet the performance requirements of each specific reactor, and clad in aluminum. Efforts to reduce ²³⁵U enrichment to less than 20% motivated implementation of uranium silicide fuel particles (U₃Si₂) in the aluminum matrix, with its higher uranium density compensating for the reactivity impacts of reducing the ²³⁵U enrichment. Currently, plate-shaped U–Mo alloy fuel clad in aluminum is being developed and qualified in the United States to achieve an even higher uranium density to allow high-performance research reactors (high neutron flux, implying high power density) to be converted to fuel with enrichment less than 20% ²³⁵U. Another fuel common to TRIGA research reactors is uranium-zirconium hydride (U–ZrH_x), which is a form of metallic uranium particle dispersed in ZrH_x with the overall H/Zr stoichiometry nominally around 1.6. This fuel composition is unique in that a moderator is intimately mixed with the fissile material. Research reactor fuels are described in greater detail by Cole et al. (2021a,b).

Fast reactor fuel: Fast reactors have been fueled predominantly by MOX, (U,Pu)O₂ with Pu contents of 25–30 wt% of the heavy metal, but also by UO₂ and metallic uranium alloys such as U–Mo and U–Zr. Other fuel compositions that have been proposed and studied to varying extents include U-Pu-Zr, uranium nitride (UN), uranium-plutonium nitride (U,Pu)N, uranium carbide (UC, U₂C₃), and uranium-plutonium carbide (U,Pu)C/(U,Pu)₃C₂. Each of the fuel compositions brings different fuel performance considerations, with fuel stoichiometry of the ceramic fuel types and the interdiffusion of the metallic fuel alloys with the metallic cladding being important aspects to address. More detail is available on ceramic fast reactor fuel (Kato, 2021; Pastore and Toptan, 2021; and Jensen and Woolstenhulme, 2021) and on metallic fast reactor fuel (Porter and Crawford, 2021; Novascone et al., 2021; and Jensen and Woolstenhulme, 2021).

High-temperature gas reactor fuel: TRISO fuel resulted from development efforts seeking to reduce requirements for a reactor containment building by incorporating robust fission product containment into the fuel itself. TRISO fuel makes use of spherical UO₂ or uranium oxy-carbide, UCO, fuel particles coated by layers of carbon, pyrolytic graphite and silicon carbide. The containment is being proven through testing to be sufficiently robust to allow the fuel to remain at reactor-accident temperatures for extended periods of time without significant release of fission products. More information on TRISO fuel appears in Helmreich and Hunn (2021) and Gerczak (2021).

Fuel geometries

An example of a boiling water reactor (BWR; see Hamon, 2021) fuel design appears in Fig. 2. For convenience, the fuel rods are assembled as a bundle of rods to facilitate fuel handling (i.e., handling bundles of many rods is more efficient than handling very large number of separate fuel rods). A lower tie plate in the fuel assembly affixes the fuel rods into position at the bottom of the bundle, and grid spacers placed at different elevations along the length of the bundle hold the fuel rods in their respective positions, ensuring the rods maintain spacing for coolant flow. The lower tie plate also includes features for the fuel assembly interface with the reactor core grid, while the upper tie plate anchors the fuel rods at their upper end and includes design features that allow handling of the fuel assemblies. A square box, or channel, is placed around the fuel bundle to provide a defined coolant

Fig. 2 Rendering of the GNF-2 fuel assembly, which is shown in a horizontal orientation rather than the vertical in-service orientation. LWR fuel assemblies such as this range in length from roughly 3.5 to 4.5 m. Courtesy Global Nuclear Fuel.

geometry through the fuel bundle, to add structured load paths to the fuel assembly and the assembled reactor core, and to reduce any deleterious impact of one fuel bundle on another. Additional design features and components were introduced into the fuel assembly to optimize fuel utilization and improve reactor stability in the boiling water environment; those features include incorporation of water rods (hollow tubes) in place of selected fuel rods to allow water to be directed into the top of the fuel bundle to improve neutron moderation in the upper part of the fuel bundle, thereby improving fuel utilization. Partial-length fuel rods are used in selected bundle positions to replace fuel volume with water volume in the upper part of the bundle, to improve fuel utilization and fuel bundle pressure drop. Other features include design of the grid spacers to improve boiling transition behavior in the fuel bundle (by improving boiling characteristics at the fuel rod surface) and incorporation of debris filters into the fuel bundle coolant inlet in the lower tie plate to reduce fuel rod debris fretting. Finally, optimization of thermal-hydraulic performance and pressure drop within the fuel bundle improves reactor stability of modern BWR fuel designs. [Cantonwine and Rand \(2021\)](#) provides detail on the irradiation performance of LWR fuel, including BWR fuel.

Sodium-cooled fast reactor (SFR) fuel is similarly designed as bundles of rods, as seen in [Figs. 3 and 4](#). Most SFRs use hexagonal bundle geometry, rather than square bundle arrays as used in LWRs, primarily to reduce coolant-to-fuel volume ratio (and thereby harden the neutron spectrum), so the fuel rod bundles are enclosed in a hexagonal duct (or “hex can”) to form fuel assemblies. The hexagonal duct functions in a manner similar to the square channels used for BWR fuel: to provide structured load paths for the fuel bundle, to define the coolant flow geometry for the fuel bundle, and to mitigate or reduce any deleterious impacts between fuel bundles. Similarly, SFR fuel assemblies are equipped with components at the top of the assembly to allow fuel handling and at the bottom of the assembly to interface with the reactor core grid and to allow the right amount of coolant into the fuel bundle under design-basis conditions. SFR fuel differs, however, in the means used to ensure spacing of fuel rods, which is accomplished using wires helically wrapped around the fuel rods. The helical wrapping allows coolant to flow upward between the rods and induces coolant mixing between fuel rods to reduce variation in coolant temperature across the section of the fuel bundle. Because SFR coolant is intended to stay in the liquid phase and there is no need to moderate the neutrons, unlike the coolant in BWRs, and because SFR fuel rods are shorter (~ 1 m) than in LWRs (3–4 m), fewer flow-optimizing features are needed in the fuel bundle. However, the higher neutron energy in fast-spectrum reactors induces more neutron damage in reactor components and structural materials than is typical of LWRs, so SFR fuel assemblies often include stainless steel reflectors (or shields) above and below the fuel rods to reduce neutron flux incident on structures outside the fuel assemblies. Information on irradiation performance of fast reactor fuel can be found in [Jensen and Woolstenhulme \(2021\)](#).

An example of a TRISO fuel particle is shown in [Fig. 5](#), in which the coated layers (described in detail by [Helmreich and Hunn, 2021](#)) are clearly visible. The fuel kernel, UCO in [Fig. 5](#) but UO_2 has been used in other fuel designs, lies in the center of the sphere and is coated with layers of pyrolytic carbon and SiC to provide chemical and physical accommodation for and containment of fission products. The size of typical TRISO particles and their consolidation into a cylindrical compact can be seen in [Fig. 6](#). Another design uses spherical graphite compacts of TRISO fuel particles, to form a ball or “pebble” that is coated with a graphite “crust.” The density of the fuel particles within the compact or pebble is a key design feature, with higher densities favored for increasing reactor power density and reducing core size but difficult to achieve due to degrading structural and dimensional integrity of the compact. For some high-temperature gas reactor designs ([Futterer, 2021](#)), the compacts are stacked into fuel channels drilled into hexagonal graphite blocks which are assembled to form the core assembly. Other reactors use beds of pebbles, with the interstitial space between pebbles sufficient for coolant flow and heat removal. Reactor concepts that use solid TRISO fuel with molten salt coolant offer the prospect for higher reactor power density, because the higher heat capacity of molten salt coolant over helium provides more efficient heat transfer from the core. [Gerczak \(2021\)](#) provides information on the behavior of TRISO fuel in high-temperature gas reactors.

Section overview

This section of the Encyclopedia presents an overview of technologies important to the front end of the nuclear fuel cycle and to utilization of nuclear fuel in reactors. The technologies addressed have varied maturity. For example, technology and practice for mining, extracting, converting, and enriching uranium and for producing, transporting, and using LWR fuel are commercialized and deployed by a global industry. In fact, many of the products in the LWR fuel supply chain are commodities, with value obtained at the margins for sellers and buyers. These commercialized technologies determine the fuel cycle economics of LWR power generation and set the standard to be improved upon by any new fuel cycle or reactor technology.

Some fuel technologies are less mature. It remains to be seen whether new LWR fuel designs intended to improve resistance to reactor accidents and off-normal conditions will offer operating cost reduction (by reducing the need to maintain specialized safety equipment in the plants) to compensate for anticipated increase in fuel cycle cost. Although SFRs are not deployed on an industrial scale, the economic potential of oxide or metallic fuels in SFRs is relatively well known. The economic prospects of molten salt fuel technology for MSRs, based on principles of molten salt chemistry and experience with experimental reactors operated in the 1960s (Gakhar et al., 2021), are encouraging but somewhat speculative at this point.

Chapters in this section will provide the reader with some background on the technology and market considerations for the front-end (i.e., the extraction and processing of uranium and thorium for subsequent fabrication of specific fuel products). Most of the discussion and examples will address uranium-based fuel, because the uranium fuel market is the most developed. Content on uranium and thorium resources and extraction is provided by Hore-Lacy (2021), Conca (2021), and Haneklaus (2021). Uranium enrichment and conversion are addressed by Hogan (2021).

Fabrication of specific fuel designs is addressed in chapters that address ceramic fuel (Kato, 2021), metal fuel (Porter and Crawford, 2021), research reactor fuel (Cole et al., 2021a,b), and TRISO fuel (Helmreich and Hunn, 2021). Other fuel types, designed for use in power generating reactors, with significant development and demonstration, though not yet adopted commercially, include TRISO coated particle fuel for use in high-temperature gas reactors (and recently-proposed salt cooled reactors; see Gakhar et al., 2021), uranium-plutonium dioxide ($\text{UO}_2\text{-PuO}_2$) fuel and uranium alloy or uranium-plutonium alloy fuel for fast-spectrum reactors. Each of these fuel types has required unique fabrication approaches, particularly as conventional fabrication processes were adapted to nuclear fuel, and these fabrication approaches are described in this section.

Finally, because processing and handling of fissile material in the fuel cycle brings nuclear safety considerations not encountered in other industries, a chapter is provided to address nuclear criticality safety (Bowen, 2021).

Because the fuel cycle theme is so broad, some associated topics are addressed in other sections of this Encyclopedia. Specifically, the approaches used to design nuclear reactor cores for operating cycles (i.e., the duration of operation time between fuel reloading, or replacement of used fuel with fuel) are described by Shwageraus (2021) and Wigeland et al. (2021) as is the technology for addressing used nuclear fuel to prepare its constituents for disposal (e.g., Glatz, 2020). Other authors address the technology available to remove useable constituents from used nuclear fuel for reintroduction back into the nuclear fuel cycle (Senentz, 2021; Marin, 2021; Boullis and Chabert, 2021; Miguiditchian, 2021), some of which has been commercially deployed in nations such as France and United Kingdom, but which has not yet reached commercial deployment in other nations, such as the United States and Japan.

Geology and mines

Uranium is a relatively common element in the crust of the Earth (very much more than in the mantle). It is a metal approximately as common as tin or zinc, and it is a constituent of most rocks and even of the sea ([Herring, 2021](#)).

Uranium deposits worldwide are grouped into 15 major categories of deposit types based on their geological setting. The most recent geological classification has been defined by the International Atomic Energy Agency ([Bruneton et al., 2014](#)) and is adopted in the following edition of *Red Book* (2014). The deposit types have fundamental characteristics and recognition criteria and in that respect, while mainly named by host rock, the types are essentially empirical models, based on observable characteristics.

A comprehensive listing of world uranium deposits from a purely geological perspective includes much low-grade mineralization which is subeconomic. There is very little recovery of uranium from the three deposit types with the largest estimated totals—lignite, black shale and phosphate. Three of the next most-abundant comprise most of the 6.1 million tonnes of economic resources listed in the 2018 *Red Book* ([OECD NEA & IEA, 2018](#)), and contribute much of the world's supply of uranium today: sandstone, iron-oxide breccia, and Proterozoic unconformity.

Sandstone deposits

Sandstone uranium deposits occur in medium to coarse-grained sandstones deposited in a continental fluvial or marginal marine sedimentary environment. Impermeable shale/mudstone units are interbedded in the sedimentary sequence and often occur immediately above and below the mineralized sandstone. Uranium is precipitated under reducing conditions caused by a variety of reducing agents within the sandstone including: carbonaceous material, sulfides (pyrite, H₂S), hydrocarbons, and interbedded

basic volcanic ash with abundant ferro-magnesian minerals (e.g. chlorite). There are several sub-types of sandstone deposits, often mixed.

Sandstone deposits constitute about 18% of world uranium resources and 41% of known deposits, and are of major economic importance in Kazakhstan, Uzbekistan, Australia, the United States and Niger. Orebodies of this type are commonly low to medium grade (0.05–0.35% U) and individual orebodies are small to medium in size (ranging up to a maximum of 50,000 tU). Imouraren (Niger) and some Kazakh deposits are larger. Several sub-types are mined by in situ leach (ISL) methods. The main primary U minerals are uraninite and coffinite.

The United States has large resources in sandstone deposits in the Western Cordillera region, and most of its uranium production has been from these deposits, recently by ISL mining. The Powder River Basin in Wyoming, the Colorado Plateau and the Gulf Coast Plain in south Texas are major sandstone uranium provinces.

Polymetallic iron-oxide breccia complex deposits

Olympic Dam is the world's largest deposit of uranium, and accounts for the major part of Australia's uranium resources, though it is only recovered as a by-product with copper. Both it and Carrapateena occur in a hematite-rich granite breccia complex in the Gawler Craton, overlain by approximately 300 m of flat-lying sedimentary rocks of the Stuart Shelf geological province.

The central core of the Olympic Dam complex is barren hematite-quartz breccia, flanked by zones of intermingled hematite-rich breccias and granitic breccias. These zones are approximately 1 km wide and extend almost 5 km. Virtually all the economic copper-uranium mineralization is hosted by these hematite-rich breccias. The deposit contains iron, copper, uranium, gold, silver, rare earth elements and fluorine. Only copper, uranium, gold, and silver are recovered. Uranium grades average from 0.07 to 0.035% U, the higher-grade mineralization being pitchblende. Copper grades average 2.7% for proved reserves and 2.0% for probable reserves. Details of the origin of the deposit are still uncertain, though the principal mechanisms which formed the breccia complex are considered to have been hydraulic fracturing, tectonic faulting, chemical corrosion, and gravity collapse.

Proterozoic unconformity deposits

Unconformity-related deposits arise from geological changes occurring close to major geological unconformities from the Proterozoic era. Below the unconformity, the metasedimentary rocks which host the mineralization are usually faulted and brecciated. The overlying younger Proterozoic sandstones are usually undeformed. Unconformity-related deposits constitute about one third of the western world's uranium resources and they include some of the largest and richest deposits. Minerals are uraninite and pitchblende associated with strong quartz dissolution. The main deposits occur in Canada (the Athabasca Basin, Saskatchewan and Thelon Basin, Northwest Territories); and Australia (the Alligator Rivers region in the Pine Creek Geosyncline, Northern Territory and Rudall River area, Western Australia).

All of Canada's uranium production in Saskatchewan over the last 40 years is from unconformity-related deposits—Key Lake, Cluff Lake, Rabbit Lake, McClean Lake, McArthur River and Cigar Lake deposits, with some ore around 20% uranium. The deposits in the Athabasca Basin occur below, across and immediately above the unconformity, with the highest grade deposits situated at or just above the unconformity (e.g. Cigar Lake and McArthur River). In the Alligator Rivers region, the known deposits (Ranger, Jabiluka, Koongarra and Nabarlek) are hosted in the basement structure below the unconformity and are generally lower grade. Strata-bound structure-controlled unconformity deposits include the low-grade Chitral and Lambapur deposits, Cuddapah Basin, India.

Most uranium is mined as the primary mineral in any mining project, but a significant amount is obtained as by-product, notably at Olympic Dam in South Australia, which is in fact the world's largest known orebody for uranium, though it is primarily a copper mine. In addition, there is potential production from so-called unconventional resources. This article is mainly focused on situations where uranium is primary, or a significant by-product.

Major uranium mines

Mining methods have been changing. In 1990, 55% of world production came from underground mines, but this reduced dramatically to 33% in 1999. From 2000 the new Canadian mines increased it again. In situ leach (ISL, or in situ recovery (ISR)) mining has been steadily increasing its share of the total, mainly due to Kazakhstan, and in 2019 accounted for over half of production. In 2019 production was as follows:

<i>Method</i>	<i>Tonnes U</i>	<i>%</i>
In situ leach (ISL)	30,339	57%
Underground and open pit (except Olympic Dam)	19,607	36%
By-product (including Olympic Dam, underground)	3710	7%

Table 1 The largest-producing uranium mines in 2019.

Mine	Country	Main owner	Type	Production (tonnes U)	% of world
Cigar Lake	Canada	Cameco/Orano	Underground	6924	13
Husab	Namibia	Swakop Uranium (CGN)	Open pit	3400	6

<i>Top 10 total</i>				30,032	56%

Unconventional resources

In addition to the 6.1 million tonnes of uranium in the world's known recoverable resources, there are substantial amounts comprising what is known as "unconventional resources." Such unconventional resources, from which uranium can be produced in conjunction with other metals, as by-product, have accounted for over 11% of historical uranium production.

The main unconventional resource for uranium is *rock phosphate*, or phosphorite, and some 20,000 tU has been recovered as a by-product of agricultural phosphate production to the 1990s, but it then became uneconomic. Estimates of the amount available range from 9 to 22 million tonnes of uranium, though the 2018 *Red Book* tabulates only about 8 million tonnes.

With uranium as a minor by-product of phosphates, the potential supply is tied to the economics of phosphate production, as well as uranium price, coupled with the environmental benefits of removing uranium from the waste stream and/or product. World phosphorous pentoxide (P_2O_5) production capacity from about 250 Mt. of rock phosphate is about 50 million tonnes per year. From 1981 to 1992 US production from central Florida's phosphate deposits as by-product averaged just over 1000 tU per year, comprising up to 20% of US total, then fell away sharply and finished in 1998. Morocco has by far the largest known resources of uranium in phosphate rock (Phosenergy, n.d.).

Rare earth element (REE) deposits are another such unconventional resource. REEs play a critical role in the application of many modern technologies, including magnetic resonance imaging (MRI) machines, satellites, batteries, LED screens and solar panels. China is the leading supplier of REEs, giving rise to commercial pressure for development of deposits elsewhere.

REEs are a set of 17 chemical elements in the periodic table, specifically the 15 contiguous lanthanides plus the lighter scandium and yttrium. Scandium and yttrium are considered REEs since they tend to occur in the same ore deposits as the lanthanides and exhibit similar physical and chemical properties. REEs are in fact relatively abundant in the Earth's crust, but are rarely found in concentrations that are economically exploitable. REE resources occur in four primary geological settings: carbonatites, ion-absorption clay deposits, igneous systems and monzanite-xenotime placer deposits. REE resources are usually reported as rare earth oxides (REO).

Kvanefeld in Greenland is the main REE deposit with major potential for uranium production, with Sorensen, Zone 3 and Steenstrupfeld orebodies in the same Ilimaussac intrusive complex. Those four deposits have a total of 228,000 tU (May 2015, JORC-compliant), nearly half of it measured and indicated resources. Greenland Minerals (<http://www.ggg.gl>) has an agreement with Chinese company Shenghe Resources which will enable development to proceed.

Black (Alum) shales are another unconventional resource with some attempts being made to exploit them. The 2018 *Red Book* tabulates about 300,000 tU in Sweden and mentions 24,000 tU in Finland at the Sotkamo mine of Terrafame Oy, for which the government granted a permit in 2020 for uranium recovery as by-product by heap leaching. Uzbekistan has 32,900 tU in black shales, attracting Chinese interest.

Exploration: Identifying resources

This section is drawn substantially from Kyser (2016).

Exploration for uranium deposits, as with any type of geological search, requires the integration of regional geology, structural geology, geophysics and geochemistry and must embrace new technologies and research results, particularly ore genesis models, to be effective. Political risks must also be factored in.

Exploration effort is focused on areas that have the potential to host economic uranium deposits. The geological assessment of the uranium mineral endowment is a knowledge-based activity that is based on understanding deposit models and the probability of their occurrence. A great deal depends on developing understanding of how orebodies were formed millions or billions of years ago. This knowledge then enables interpretation of evidence collected as described below.

A variety of methods are normally used for exploration, including a balance of geological mapping, remote sensing, geophysics, and geochemistry, followed by actually drilling to investigate anomalies which may be possible orebodies.

Geological mapping

Some broad-scale mapping is normally done by governments. Further, more detailed, mapping is required to supplement what is available on the public record. It is focused on structures that are evident and what the structural evolution of the area is understood to be. Structures are controlling many types of uranium deposits related to hydrothermal fluid circulation.

Regional-scale structural results from mapping can be integrated with geophysical methods that identify possible structures at depth based on physical anomalies of the rocks. Although structure is critical in the formation of the deposits, the vast majority of structures with seemingly appropriate characteristics are not mineralized. Mapping is also used to characterize the cover, including Quaternary geology, soil character and type, and character of vegetation.

Remote sensing

This involves acquiring, processing and interpreting spectral information about the Earth's surface, and recording interactions between matter and electromagnetic energy, mainly from satellites. Among the remote sensing data to be integrated in evaluating prospective areas are radiometry as part of airborne geophysics, and other means of identifying radiometric anomalies. These techniques detect energy reflected and emitted from the Earth's surface from minerals, vegetation, soils, etc., in selected wavelengths.

Geophysical methods

These vary with the type of uranium deposit because different aspects of the mineralisation are targeted. The mainstay of exploration geophysics for uranium deposits is gamma ray radiometry and spectrometry used from airborne regional to local detailed surveys. This is followed up with down-hole logging of gamma radiation and measurement on outcrops using hand-held units. Gamma data is normally collected as part of airborne magnetic surveys with magnetic contrasts used to reveal the general geology. Airborne gamma-ray spectrometry directly indicates U, K, and Th in surficial material.

Magnetics are used to map basement lithologies in basin-hosted systems. Various electromagnetic (EM) techniques are used to image graphitic conductors that are occasionally associated with unconformity-related deposits, paleochannels in sandstone-hosted systems, and alteration haloes in basin related systems. Ground EM surveys are used routinely to follow-up airborne surveys with deeper penetration through any sandstone cover, and they often provide detailed assessments of targets of interest.

Gravity measurement reflects structures and alteration because of changes and breaks in lithology. Seismic techniques can reveal structures, areas of alteration, stratigraphy and depth to basement.

Measuring radon emanation can indicate buried mineralisation, due to the ability of radon, a gaseous progeny of from decay of U-238, to migrate to the surface. Most instrumentation relies on alpha particle detection.

In areas such as sedimentary basins where the deposits tend to be well covered, geophysical techniques are powerful tools to see physical anomalies beneath.

Prompt Fission Neutron (PFN) borehole logging technology directly measures the content of uranium in boreholes, overcoming the problem of disequilibrium which limits the interpretation of uranium concentrations using gamma logging tools. This is particularly important in placer deposits such as in palaeochannels.

Although geophysics costs can be substantial, drilling is much more so, and a great deal of information about hidden geology can be obtained.

Geochemical methods

There are two distinct processes that expand the geochemical footprint of a deposit: (1) primary dispersion, which provides information on alteration and primary element dispersion associated with the original formation of the ore; and (2) secondary dispersion, which provides clues about element migration from alteration and ore zones well after emplacement.

During primary dispersion, components in the mineralizing fluids permeate into the country rock, which alters primary minerals and elevates the concentrations of "pathfinder" elements. These enrichments relative to background concentrations are sometimes evident in the geochemistry of rocks up to several kilometers away from the uranium mineralisation. Hydrothermal alteration minerals associated with mineralizing fluids can be detected.

The levels of uranium concentration that can be considered anomalous vary according to the deposit type and its environment. In U-rich granites, significant anomalies should be above some tens of ppm, the granites having themselves a background uranium concentrations of 10–30 ppm, whereas for unconformity related deposits, anomalies of a few ppm in the sandstone may be meaningful because most of the sandstone has an average uranium content below one ppm.

In contrast to primary dispersion that occurs with the ore-forming process, secondary dispersion occurs subsequently via the mobilization of ore or alteration elements into the environment around the deposits. Tracing element migration in the near-surface environment involves understanding the secondary dispersion of elements.

Most ore deposits are potential havens for microbes that can mobilize elements during secondary dispersion. Microbe-mobilized elements can migrate to the surface, particularly along fractures and faults, and make their way into the biosphere. Their specific element and isotope signatures can reflect the deposit at depth.

Mineralogy is an excellent exploration guide when specific alteration minerals are developed in association with ore deposit formation. The mineralogy of the uranium is also critical for evaluating the processing costs for uranium extraction.

Chemical analysis of groundwater can be a useful strategy for regional exploration for uranium in reduced sediments in palaeochannels.

Groundwater samples collected from boreholes tens of meters from unconformity-related uranium mineralisation have consistently high levels of uranium, radium, radon and helium. Biogeochemistry of plants indicate that tree roots can extract anomalous uranium from groundwater that may reflect deposits at 300 m depth.

Lake water and sediment geochemistry and radiometric prospecting are significant tools in early regional exploration for uranium deposits in Canada due to the mobility of uranium in surface waters, which allows the element to disperse widely from its source.

Drilling

After targets have been identified by integrating favorable geophysical and geochemical results, the next stage of exploration is drilling. Most alteration halos associated with deposits are barren. Directional drilling allows several intersections to be made from a single pilot hole, reducing drilling costs and improving target precision.

Given that drill hole samples represent an actual physical sample of the subsurface and are among the costliest aspects of exploration, interpreting them needs to be linked with the geological, geophysical, and geochemical data. Core or cuttings are logged to reveal lithology and stratigraphy. In addition, down hole electromagnetics, radiometrics, and neutron tomography should be done if possible.

At each step, the property should continually be re-evaluated so that informed decisions about investing in further steps can be made.

Quantification of resources

Total world resources of uranium, as with any other mineral or metal, are not known exactly. The only meaningful measure of long-term security of supply is the known reserves in the ground capable of being mined.

An orebody is, by definition, an occurrence of mineralization from which the metal is economically recoverable. Orebodies, and thus measured resources—the amount known to be economically recoverable from orebodies—are therefore relative to both costs of extraction and market prices. For example, at present neither the oceans nor any granites are orebodies, but conceivably either could become so if prices were to rise sufficiently. At 10 times the current price, seawater, for example, might become a potential source of vast amounts of uranium. Thus, any predictions of the future availability of any mineral, including uranium, which are based on current cost and price data, as well as current geological knowledge, are likely to prove extremely conservative (Table 2).

Uranium has been successfully mined since the 1940s. Historical uranium production is generally well known, though uncertainties remain about the amount mined in the Soviet Union between 1945 and 1990. Table 3 summarizes historical production. World Nuclear Association has estimated production in countries where data is unavailable.

Reporting uranium resources

The following are internationally-recognized categories based on Australia's JORC code, which the Canadian NI 43-101 code follows.

A "mineral resource" is a known concentration of minerals in the Earth's crust with reasonable prospects for eventual economic extraction. Mineral resources are sub-divided, in order of increasing geological confidence, into inferred, indicated and measured categories.

- An "inferred" mineral resource is that part of a mineral resource for which tonnage, grade and mineral content can be estimated with only a low level of confidence. The information on which it is based is limited, or of uncertain quality and reliability.
- An "indicated" mineral resource is that part of a mineral resource for which tonnage, grade and mineral content can be estimated with a reasonable level of confidence. It is based on exploration, sampling and testing information which is adequate to assume but not confirm geological and/or grade continuity.
- A "measured" mineral resource is that part of a mineral resource for which tonnage, physical characteristics, grade and mineral content can be estimated with a high level of confidence. It is based on detailed and reliable exploration, sampling and testing information with locations spaced closely enough to confirm geological and grade continuity.

A "mineral" reserve (or ore reserve) is the economically mineable part of a measured and/or indicated mineral resource. It allows for dilution and losses which may occur when the material is mined. Appropriate assessments and studies will have been carried out,

Table 2 Uranium resources by country in 2017.

	<i>Tonnes U</i>	<i>Percentage of world</i>
Australia	1,818,300	30%
Kazakhstan	842,200	14%
Canada	514,400	8%

and include consideration of realistically assumed mining, metallurgical, economic, marketing, legal, environmental, social and governmental factors. Mineral or ore reserves are sub-divided in order of increasing confidence into probable mineral/ore reserves and proved mineral/ore reserves.

- A “probable” mineral reserve (or probable ore reserve) is the economically mineable part of an indicated mineral resource. Studies to at least pre-feasibility level will have been carried out, demonstrating that extraction could reasonably be justified.
- A “proved” mineral reserve (or proved ore reserve) is the economically mineable part of a measured mineral resource. Studies to at least pre-feasibility level will have been carried out, demonstrating that extraction is justified.

Using uranium resources

The world’s power reactors, with combined capacity of some 400 GWe, require about 65,000 t of uranium from mines or secondary sources each year. While this capacity is being run more productively, with higher capacity factors and reactor

power levels, the uranium fuel requirement is increasing, but not necessarily at the same rate. The factors increasing fuel demand are offset by a trend for higher burn-up of fuel and other efficiencies, so demand is steady. (Over the years 1980 to 2008 the electricity generated by nuclear power increased 3.6-fold while uranium used increased by a factor of only 2.5.)

The world's present measured resources of uranium (6.1 Mt) in the cost category less than three times present spot prices and used only in conventional reactors, are enough to last for about 90 years. This represents a higher level of assured resources than is normal for most minerals. Further exploration and higher prices will certainly, on the basis of present geological knowledge, yield further resources as present ones are used up.

Reducing the tails assay in enrichment reduces the amount of natural uranium required for a given amount of fuel. Reprocessing of used fuel from conventional light water reactors also utilizes present resources more efficiently, by a factor of about 1.3 overall. The 2018 *Red Book* recognized these trends, along with more efficient plant operation, and as a result of which, the report's generic reactor fuel consumption was reduced from 175 tU per GWe year at 0.30% tails assay (2012 report) to 160 tU per GWe year at 0.25% tails assay (2016 and 2018 reports). The corresponding U_3O_8 figures are 206 t and 189 t. Note that these figures are generalizations across the industry and across many different reactor types.

Today's nuclear reactors use less than 1% of the mined uranium. About 89% is put aside as depleted uranium from enrichment, and 11% is fed into the reactor as actual fuel. Of this, 2.5% is fissioned (i.e. 0.275% of original) and a similar amount is converted into plutonium, about half of which is fissioned, so total of about 0.4% of original uranium. In a fast neutron reactor potentially all the mined uranium can be used, and a figure of 50 times the energy output is often quoted. In any kind of reactor a limitation of fuel use is the build-up of neutron poisons in the fuel.

So a very significant change in uranium use is likely if and when many countries replace present reactor fleets with fast neutron reactors. Instead of using less than 1% of the uranium that is mined, they will be able to use a majority of it by converting U-238 to plutonium-239 in the reactor core on a much larger scale than at present (where about one third of the power typically comes from Pu-239). This will potentially make uranium mining redundant, given that there will be over two million tonnes of depleted uranium conveniently available as potential fuel by mid-century.

About half of the Generation IV reactors being developed internationally are fast neutron reactors. However, practically all the reactors planned and under construction today are Generation III models with an expected operating life of 60 years, and they will be predominant at least until mid-century.

Sustainability of uranium supply

The sustainability of uranium supply for world nuclear power requirements is affected by three things:

- gains in geological knowledge and understanding of mineral deposits;
- new technologies utilized to discover, process and use them;
- economic principles, particularly where resources are thought of only in present terms, not in terms of what will be economic through time, nor with concepts of substitution in mind.

The following diagram summarizes the basic dynamics involved:

Economic Adjustments in Uranium Supply and Use

Today's reactor fuel requirements are met almost entirely from primary supply (direct mine output) with some from secondary sources: commercial stockpiles, nuclear weapons stockpiles, recycled plutonium and uranium from reprocessing used fuel, and some from re-enrichment of depleted uranium tails (left over from original enrichment).

These various secondary sources make uranium unique among energy minerals.

Mining and milling uranium ore

Uranium mines operate in some 20 countries, though in 2018 some 51% of world production came from just 10 mines in four countries (see [Table 1](#)).

Most of the uranium ore deposits at present supporting these mines have average grades in excess of 0.10% of uranium—that is, greater than 1000 ppm. In the first phase of uranium mining to the 1960s, this would have been seen as a respectable grade, but today some Canadian mines have huge amounts of ore up to 20% U average grade. Other mines however can operate successfully with very low-grade ores, down to about 0.02% U.

Some uranium is also recovered as a by-product with copper, as at Olympic Dam mine in Australia, or as by-product from the treatment of other ores, such as the gold-bearing ores of South Africa, or from phosphate deposits such as Morocco and Florida. In these cases the concentration of uranium may be as low as a tenth of that in orebodies mined primarily for their uranium content. An orebody is defined as a mineral deposit from which the mineral may be recovered at a cost that is economically viable given the current market conditions. Where a deposit holds a significant concentration of two or more valuable minerals then the cost of recovering each individual mineral is reduced as certain mining and treatment requirements can be shared. In this case, lower concentrations of uranium than usual can be recovered at a competitive cost.

Generally speaking, uranium mining is no different from other kinds of mining unless the ore is very high grade. In this case special mining techniques such as increased dust suppression, and in extreme cases remote handling techniques, are employed to limit worker radiation exposure and to ensure the safety of the environment and general public.

Searching for uranium is in some ways easier than for other mineral resources because the radiation signature of uranium's decay products allows deposits to be identified and mapped from the air. See above section on Exploration.

Open pit and underground mining

Where orebodies lie close to the surface, they are usually accessed by open cut mining, involving a large pit and the removal of much overburden (overlying rock) as well as a lot of waste rock. Where orebodies are deeper, underground mining is usually employed, involving construction of access shafts and tunnels but with less waste rock removed and less environmental impact. In either case, grade control is usually achieved by measuring radioactivity as a surrogate for uranium concentration. (The radio-metric device detects associated radioactive minerals which are decay products of the uranium, rather than the uranium itself—see later footnote.)

At Ranger in north Australia, Rössing and Husab in Namibia, and most of Canada's Northern Saskatchewan mines through to McClean Lake, the orebodies have been accessed by open cut mining. Other mines such as Olympic Dam in Australia, McArthur River, Rabbit Lake and Cigar Lake in Northern Saskatchewan, and Akouta in Niger are underground, up to 600 m deep. At McClean Lake and Ranger, mining was planned to be completed underground.

In situ leach (ISL) mining

Some orebodies lie in groundwater in porous unconsolidated material (such as gravel or sand) and may be accessed simply by dissolving the uranium and pumping it out—this is in situ leach (ISL) mining (also known in North America as in situ recovery (ISR)). It can be applied where the aquifer in which the orebody lies is confined vertically and ideally horizontally. Buried paleochannels (ancient river channels) are typical. It is not licensed where potable water supplies may be threatened.

ISL mining means that removal of the uranium minerals is accomplished without any major ground disturbance, so it is certainly the mining method with least environmental impact. Groundwater from the aquifer with a lot of oxygen added is circulated back through the enclosed underground aquifer which holds the uranium ore in loose sands. This leaching solution is weakly acidified or alkaline and it dissolves the uranium before being pumped to the surface treatment plant where the uranium is recovered as a precipitate. Most US and Kazakh uranium production is by this method.

In Australian ISL mines the oxidant used is hydrogen peroxide and the complexing agent sulfuric acid to give a uranyl sulfate in the pregnant liquor. Kazakh ISL mines generally do not employ an oxidant but use much higher acid concentrations in the circulating solutions. ISL mines in the United States use an alkali leach to give a uranyl carbonate due to the presence of significant quantities of acid-consuming minerals such as gypsum and limestone in the host aquifers. Any more than a few percent carbonate minerals means that alkali leach must be used in preference to the more efficient acid leach, though the cost is often double.

In either the acid or alkali leaching method the fortified groundwater is pumped into the aquifer via a series of injection wells where it slowly migrates through the aquifer, leaching the uranium bearing host sand on its way to strategically placed extraction wells, where submersible pumps bring the liquid to the surface for processing.

For very small orebodies amenable to ISL mining, a small satellite plant can be set up. This does no more than provide a facility to load the ion exchange (IX) resin/polymer so that it can be trucked to the central plant some distance away in a bulk trailer for stripping. Hence very small deposits can become viable, since apart from the wellfield, little capital expenditure is required at the mine and remote IX site.

Heap leaching

Some ore, usually very low-grade (below 0.1% U), may be treated by heap leaching. Here the broken ore is stacked about 5–30 m high on an impermeable pad and irrigated with acid (or sometimes alkaline) solution over many weeks. The pregnant liquor from this is collected and treated to recover the uranium, as with ISL, usually using ion exchange. After the material ceases to yield significant further uranium, it is removed and replaced with fresh ore. Recoveries are typically 50–80%. The depleted material has the potential to cause pollution so must be emplaced securely so as not to affect surface water or groundwater. Usually this will be in mined-out pits.

Milling and processing

Conventional mines have a mill where the ore is crushed and ground to liberate the mineral particles, then leached in tanks with sulfuric acid to dissolve the uranium oxides. The solution is then processed to recover the uranium. With some South African uranium recovery from gold tailings, a pressure leach is necessary.

Sometimes a physical beneficiation process is used to concentrate the ore and increase the head grade before chemical treatment. This may be radiometric sorting as at Ranger, screening/gravity, or a new process called ablation.

Most of the ore is barren rock or other minerals which remain undissolved in the leaching process. These solids or “tailings” are separated from the uranium-rich solution, usually by allowing them to settle out. The remaining solution is filtered and the uranium is recovered in some form of ion exchange (IX) or solvent extraction (SX) system. The pregnant liquor from ISL or heap leaching is treated similarly. The uranium is then stripped from this and precipitated. The final chemical precipitate is filtered and dried.

Peroxide products can be dried at ambient temperatures to produce a product containing about 80% U_3O_8 . Ammonium or sodium diuranate ($(\text{NH}_4)_2\text{U}_2\text{O}_7$ or $\text{Na}_2\text{U}_2\text{O}_7$) products are dried at high temperatures to convert the product to uranium oxide concentrate— U_3O_8 —about 85% uranium by mass. This is sometimes referred to as yellowcake, though it is usually khaki.

In the case of carbonate leaching the uranyl carbonate (UO_2CO_3) can be precipitated with an alkali, e.g. as sodium or magnesium diuranate ($\text{Na}_2\text{U}_2\text{O}_7$ or MgU_2O_7).

The product is then packed into 200-L steel drums which are sealed for shipment. The U_3O_8 is only mildly radioactive (the radiation level 1 m from a drum of freshly-processed U_3O_8 is about half that—from cosmic rays—on a commercial jet flight). In ISL mills the process of uranium recovery is very similar, without the need for crushing and grinding.

Tailings management and mine rehabilitation

From open cut mining, there are substantial volumes of barren rock and overburden waste. These are placed near the pit and either used in rehabilitation or shaped and revegetated where they are.

Uranium minerals are always associated with more radioactive elements such as radium and radon in the ore which arise from the radioactive decay of uranium over a few million years. Therefore, although uranium itself is barely radioactive, the ore which is mined, especially if it is very high-grade such as in some Canadian mines, is handled with some care, for occupational health and safety reasons.

Mining methods, tailings and run-off management and land rehabilitation are subject to Government regulation and inspection. For instance in Australia the Code of Practice and Safety Guide: Radiation Protection and Radioactive Waste Management in Mining and Mineral Processing was published in 2005, and updated in 2015.

Solid waste products from the milling operation are tailings, ranging in character from a very fine material to coarse sands. They comprise most of the original ore and they contain most of the radioactivity in it.¹ In particular they contain all the radium present in the original ore. At an underground mine they may be first cycloned to separate the coarse fraction which is returned underground and used for underground fill. The balance is pumped as a slurry to a tailings dam, which may be a worked-out pit as at Ranger and McClean Lake, or an engineered structure.

When radium undergoes natural radioactive decay one of the products is radon gas. Because radon and its decay products (daughters) are radioactive and because the ground rock comprising the tailings is now on the surface, measures are taken to minimize the emission of radon gas. During the operational life of a mine the material in the tailings dam is often kept covered by water to reduce surface radioactivity and radon emission (though with lower-grade ores neither pose a hazard at these levels). This water needs to be recycled or evaporated since it contains radium, which is relatively soluble. Most mines adopt a “zero discharge” policy for any pollutants.

¹About 95% of the radioactivity in uranium ore is from the U-238 decay series, totaling about 150 kBq/kg in ore with 0.1% U_3O_8 (Shusterman, 2021). The U-238 series has 14 radioactive isotopes in secular equilibrium, thus each represents about 11 kBq/kg (irrespective of the mass proportion). When the ore is processed, the U-238 and the very much smaller masses of U-234 (and U-235) are removed. The balance becomes tailings, and at this point has about 85% of its original intrinsic radioactivity. However, with the removal of most U-238, the following two short-lived decay products in the uranium decay series (Th-234 and Pa-234) soon disappear, leaving the tailings with a little over 70% of the radioactivity of the original ore after several months. The controlling long-lived isotope then becomes Th-230 which decays with a half-life of 77,000 years to radium-226 followed by radon-222 (Supervising Scientist Group, Australia).

On completion of the mining operation, it is normal for the tailings dam to be covered by some two meters of clay and topsoil with enough rock to resist erosion. This is to reduce both gamma radiation levels and radon emanation rates to levels near those normally experienced in the region of the orebody, and for a vegetation cover to be established. Where possible, tailings are eventually returned to the mine pit or underground. In Canada, ore treatment is often remote from the mine that the new ore comes from, and tailings are emplaced in mined-out pits where possible, and engineered dams otherwise.

At established ISL operations, after mining is completed the quality of the remaining groundwater must be restored to a baseline standard determined before the start of the operation so that any prior uses may be resumed. Usually this is potable water or stock water (usually less than 500 ppm total dissolved solids). Contaminated water drawn from the aquifer is either evaporated or treated before reinjection.

In contrast to the main US operations, the water quality at the Australian ISL sites is very poor to start with, and it is quite unusable. At Beverley the original groundwater in the orebody is fairly saline and orders of magnitude too high in radionuclides for any permitted use. At Honeymoon the original water is even more saline, and high in sulfates and radium. When oxygen input and leaching are discontinued, the water quality reverts to its original condition over time.

Upon decommissioning, ISL wells are sealed or capped, process facilities removed, any evaporation pond revegetated, and the land can readily revert to its previous uses.

Mining is generally considered a temporary land use, and upon completion the area with any waste rock, overburden, and covered tailings needs to be left fit for other uses, or its original use. In many parts of the world governments hold bonds to ensure proper rehabilitation in the event of corporate insolvency.

Secondary sources of uranium

Most uranium used for nuclear power comes directly from mines, via the fuel cycle facilities which prepare it for use. Some, however, comes from what are known as secondary sources.

The most obvious secondary source is *civil stockpiles* held by utilities and governments. The amount held here is difficult to quantify, due to commercial confidentiality. At the end of 2018 some 279,000 tU total inventory was estimated for utilities—USA 43,000 t, EU 45,000 t, China 120,000 t, other East Asia and India 71,000 t (World Nuclear Association, 2019). These reserves are expected to be maintained at a fairly high level to provide energy security for utilities and governments.

Military warheads have been an important source of nuclear fuel since 1987. The United States and countries of the former USSR signed a series of disarmament treaties to reduce the nuclear arsenals of the signatory countries by approximately 80%, which enabled repurposing of their fissile inventory.

The weapons contained a great deal of uranium enriched to over 90% U-235 (i.e. up to 25 times the proportion in reactor fuel). For two decades to 2013, up to 10% of electricity produced in the United States was generated from fuel fabricated using uranium that had been converted from bomb-grade material under the so-called “Megatons to Megawatts” programme. Under the programme, enough bomb-grade material for 20,000 nuclear warheads was eliminated.

Worldwide, until 2013, the conversion of military high-enriched uranium was providing about 15% of the world’s reactor requirements.

For more information, see World Nuclear Association (<https://www.world-nuclear.org/information-library/nuclear-fuel-cycle/uranium-resources/military-warheads-as-a-source-of-nuclear-fuel.aspx>).

Recycled uranium and plutonium from reprocessing used fuel is another source, and currently saves about 2000 tU per year of primary supply, depending on whether just the plutonium or also the uranium is considered. In fact, plutonium is recycled as MOX fuel, whereas the reprocessed uranium (RepU) is mostly stockpiled, but some 16,000 t of RepU from Magnox reactors in United Kingdom has been used to make about 1650 t of enriched AGR fuel. In Belgium, France, Germany and Switzerland over 8000 t of RepU has been recycled into nuclear power plants.

For more information, see World Nuclear Association (<https://www.world-nuclear.org/information-library/nuclear-fuel-cycle/fuel-recycling/processing-of-used-nuclear-fuel.aspx>).

Re-enrichment of depleted uranium (DU, enrichment tails) is another secondary source. There is over 1.6 million tonnes of depleted uranium available, from both military and civil enrichment activity since the 1940s, most at tails assay of 0.25–0.35% U-235. Non-nuclear uses of DU are very minor relative to annual accumulation of over 50,000 tU per year. This leaves most DU available for mixing with recycled plutonium for MOX fuel or as a future fuel resource for fast neutron reactors.

However, some DU that has relatively high assay can be fed through under-utilized enrichment plants to produce natural uranium equivalent, or even enriched uranium ready for fuel fabrication. Russian enrichment plants have treated 10–15,000 t per year of DU assaying over 0.3% U-235, stripping it down to 0.1% and producing a few thousand tonnes per year of natural uranium equivalent. This Russian programme treating Western tails has now finished, but a new US one is expected to start when surplus capacity is available, treating about 140,000 t of old DU assaying 0.4% U-235.

Underfeeding at enrichment plants is a significant source of secondary supply, especially since the Fukushima accident reduced enrichment demand for several years. This is where the operational tails assay is lower than the contracted/transactional assay, and the enricher sets aside some surplus natural uranium, which it is free to sell (either as natural uranium or as enriched uranium product) on its own account. This source will provide an estimated 3500–7000 tU/year to the mid-2020s.

International fuel reserves

There have been three major initiatives to set up international reserves of enriched fuel, two of them multilateral ones, with fuel to be available under International Atomic Energy Agency (IAEA) auspices despite any political interruptions which might affect countries needing them. The third is under US auspices, and also to meet needs arising from supply disruptions. All have low-enriched uranium (LEU), typically 3.5–5% U-235.

IAEA LEU fuel bank

In December 2010 the IAEA board resolved to establish a guaranteed reserve of low-enriched uranium, the IAEA LEU Bank. It comprises a physical stock of UF₆ owned by the IAEA, is responsible for storing and protecting it. According to international norms, such a “fuel bank” must be located in a country with no nuclear weapons and be fully open to IAEA inspectors. It is located at the Ulba Metallurgical Plant in Kazakhstan.

The fuel bank hosts a potential supply of 92 t LEU (as UF₆) nominally at 4.95% enrichment for the production of fuel assemblies for nuclear power plants. The Kazakh government in April 2015 approved a draft agreement with the IAEA for this and the IAEA board then approved plans for the IAEA LEU Bank to be located at the Ulba Metallurgical Plant (UMP) at Ust-Kamenogorsk (aka Oskemen) and operated by Kazakhstan. A transit agreement with Russia for shipping LEU was also approved. An agreement between the IAEA and UMP was signed in May 2016 and the facility was formally opened at the end of August 2017. It became operational in 2019, and it awarded contracts to Orano and Kazatomprom to supply it.

Russian LEU reserve

In November 2009 the IAEA Board approved a Russian proposal to create an international “fuel bank” or guaranteed reserve of low-enriched uranium under IAEA control at the International Uranium Enrichment Centre at Angarsk. This Russian LEU reserve was established a year later and comprises 123 t of low-enriched uranium as UF₆, enriched 2.0–4.95% U-235 (with 40 t of latter), available to any IAEA member state in good standing which is unable to procure fuel for political reasons. It is fully funded by Russia, held under safeguards, and the fuel will be made available to IAEA at market rates, using a formula based on spot prices. Following an IAEA decision to allocate some of it, Rosatom will transport material to St Petersburg and transfer title to IAEA, which will then transfer ownership to the recipient. The 120 t uranium as UF₆ is equivalent to two full fuel loads for a typical 1000 MWe reactor.

American assured fuel supply

In 2005 the US government announced plans for the establishment of a mechanism to ensure fuel supply for use in commercial reactors in foreign countries where there has been supply disruption. The fuel would come from downblending 17.4 t of high-enriched uranium (HEU) to LEU. In August 2011 US Department of Energy announced an expanded scope for the program so it would also serve US utility needs, and now be called the American Assured Fuel Supply (AFS). At that point most of the downblending of the HEU had been completed, and the scheme was ready to operate. The AFS comprises 286 t of LEU (with another 60 t from downblending being sold on the market to pay for the work). Additionally, the USA has completed the process of downblending another 20.1 t of HEU. The AFS program is administered by the US National Nuclear Safety Administration, any foreign access must be through a US entity, and the fuel will be sold at current market prices. The 286 t amount is equivalent to about six reloads for a 1000 MWe reactor.

Uranium markets

All mineral commodity markets tend to be cyclical, i.e., prices rise and fall substantially over the years, but with these fluctuations superimposed on long-term trend of decline in real prices, as technological progress reduces production cost at mines. In the uranium market, however, high prices in the late 1970s gave way to depressed prices in the whole of the period of the 1980s and 1990s, with spot prices below the cost of production for all but the lowest cost mines. Spot prices recovered from 2003 to 2009, but have been weak since then.

The quoted “spot prices” through to about 2007 applied only to marginal trading from day to day and represented a small portion of supply, though since 2008 the proportion has approximately doubled, to about one quarter in the last decade. Most trade is via 3–15 year term contracts with producers selling directly to utilities at a significantly higher price than the spot market, reflecting the security of supply.² The specified price in these contracts is, however, often related to the spot price at the time of delivery. However, as production has risen much faster than demand, less long-term contracts are being written.

In 2000, primary market participants - utilities and producers—accounted for 95% of the spot market. That share decreased to two-thirds by 2005 and one-third by 2011 and it has remained 30–40% since. The rest comes from the financial community, namely traders and financiers who have moved in on the market, bringing greater liquidity and efficiency.

The reasons for fluctuation in mineral prices relate to demand and perceptions of scarcity. The price cannot indefinitely stay below the cost of production, nor will it remain at very high levels for longer than it takes for new producers to enter the market and anxiety about supply to subside.

²In May 2020 the spot price was \$33.40 per pound U₃O₈, the 5-year forward price published by UxC (www.uxc.com) was \$39.75.

U Uranium

Introduction

America, Japan, and China are racing to be the first nation to make nuclear energy completely renewable. The hurdle is making it economic to extract uranium from seawater, because the amount of uranium in seawater is practically inexhaustible.

New technological breakthroughs from the U.S. Department of Energy's (DOE's) Pacific Northwest (PNNL) and Oak Ridge (ORNL) national laboratories have made removing uranium from seawater within reach and the main question is - when will seawater extraction become the favored source of uranium for our nuclear power plants?

The world's almost 400 reactors produce about 2.5 trillion kWhs per year, about 10% of the global generation, using about 100,000 tons of U each year to do so. Given that there is approximately 4 billion metric tons of uranium in seawater now, this would produce about 40 quadrillion kWhs of electricity if extracted completely.

If humanity's electricity use stabilizes at about 40 trillion kWhs per year, then this would provide all of the world's electricity needs for 1000 years if nuclear were 100% of our source and we used the presently predominant design (Light Water Reactors; LWR) that operate with the once-through fuel cycle (and which utilizes less than 1% of the energy value of the natural uranium). New reactor designs, particularly fast reactor designs that utilize more of the energy in the fuel, will extend even further into the future the contribution of uranium to energy supply.

Because uranium extracted from seawater is replenished continuously through geochemical interactions with the Earth's crust deposited in seawater mainly via river flow, the potential for uranium supply goes well beyond the 4 billion metric tons currently in the oceans. This article provides an overview of the potential impact of seawater extraction of uranium, the technology used for seawater extraction of uranium, and the economic considerations that will determine whether or when benefits of seawater uranium will be realized. Although the context for this article is the U.S. uranium market, the considerations presented should be applicable to other uranium market situations.

Present sources of uranium

In their 2020 Annual Report, the Uranium Committee of the Energy Minerals Division of the American Association of Petroleum Geologists noted that the prices and supplies of uranium should remain favorable to resource and supply development for the near-future.

The United States' 96 reactors produce 20% of the nation's electricity, and require about 25,000 tons of U each year to do so. In contrast, 624,000,000 tons of natural gas is used to generate 34% of our electricity, and 750,000,000 tons of coal for 30%. 1000,000,000 tons of petroleum (7,200,000,000 barrels) fuels our transportation sector, the energy equivalent of 1,500,000,000 tons of coal.

The U.S. Navy also operates more than 40 ships and submarines using (the original) small modular nuclear power plants.

Since the 1990s, most of the uranium used in the United States is from other countries like Canada and Australia. This is a good thing, as the uranium ores in these countries are much higher grade than in the United States, which requires a lot less mining and refining to get the same amount of clean uranium.

There have been numerous discoveries of new high-grade uranium deposits in Canada and new low-grade deposits reported to be under development in Argentina and Peru. The main Australian uranium mine in South Australia (Hore-Lacy, 2021) has resumed operations (Figs. 1 and 2).

The world produces about 63 million kg (140 million lbs) of uranium as U_3O_8 each year. According to the United States Energy Information Administration, the U.S. produced a total of 77,000 kgs (170,000 lbs) of U_3O_8 of uranium concentrate from all domestic sources in 2019, 89% less than in 2018, which itself was 33% less than in 2017. 2018 production was primarily from six facilities: five in-situ leach plants in Nebraska and Wyoming (Crow Butte Operation, Lost Creek Project, Ross CPP, North Butte, and Smith Ranch-Highland Operation) and one underground mine.

The United States developed deposits in Wyoming and New Mexico that were sources of U for weapons programs during the Cold War. But known deposits and some new discoveries have occurred in 13 states. A new U.S. uranium district has been identified in the eastern Seward Peninsula of Alaska on the eastern margins of McCarthy Basin. Thorium and rare-earth elements have been discovered in the surrounding igneous rocks. Even Virginia has a huge untapped U deposit.

On the other hand, China will be entering the U supply arena this year with their Husab mine in Namibia. This huge deposit is expected to add 6,800,000 kg (15,000,000 lbs) of U to the market each year once it reaches full production. However, mining costs at the Husab site are above the current U price of \$67/kg (\$30/lb); however, the world is in oversupply, so the economic viability of the Husab mine remains to be seen.

In addition to those developments, the U industry in the U.S. has been buffeted by the U.S. government itself, which has sold excess U (as yellowcake or UF_6 from weapons inventories) directly into the market. It's a great way to get rid of weapons U, but with impacts to producers. In response, the Uranium Producers of America recommended that the DOE should stop all sales when the U spot market price is below about \$70/kg (\$32/lb).

The bottom line is that there is a relative abundance of U in the world, and more is discovered continually. U resources increased about 25% over the last decade, which has kept prices low.

Many hard-rock uranium deposits also contain associated REEs to the extent that co-production of raw rare earth elements (REEs), thorium, and other critical metals are underway for stockpiling, awaiting shipment to processing sites around the world.

According to the American Association of Petroleum Geologists Uranium Committee (AAPG UCOM), we have more U than we need for hundreds of years of nuclear power supplying a big portion of our energy generation. In this author's opinion, this is critical, since we need to double nuclear power to address climate change and replace coal, even as we ramp up renewables.

Fortunately, nuclear technology has not been stagnant. Newer designs for nuclear reactors include fast reactors that can burn ^{238}U and other actinides, getting well over 10 times the energy from the same amount of fuel (Stanculescu, 2021; Wigeland et al., 2020). That will extend present U supplies for thousands of years by making use of spent fuel from old reactors and depleted uranium left from previous activities including enrichment and weapons production.

Extraction of uranium from seawater

Uranium is present in seawater dissolved at very low concentrations, only about 3 parts per billion (3 micrograms/L, $\mu g L^{-1}$, or 0.00000045 oz per gallon).

Fig. 1 U.S. Domestic Uranium Production versus Imports 1950 to 2019 (US EIA, 2020b).

Fig. 2 Country Origins of U.S. Uranium for Nuclear Fuel. Note the small input from the United States (US EIA, 2020a).

At present, the approximately 350 quintillion gallons (1.4 sextillion liters) of seawater on Earth contains about 4 billion metric tons of uranium at any one time. The primary dissolved species are various uranyl carbonate complexes of U(VI), although water in confined basins such as the Black Sea generally have more in solution as reduced U(IV). The isotopic ratio of $^{235}\text{U}/^{238}\text{U}$ in seawater is the same as in the crust, about 0.007.

According to Ku et al. (1977), "Current estimations of the average world river uranium concentrations ($0.3\text{--}0.6\ \mu\text{g L}^{-1}$) and $^{234}\text{U}/^{238}\text{U}$ [radioactivity] ratios (1.2–1.3) and of the diffusional ^{234}U influx from sediments ($0.3\ \text{dpm cm}^{-1}\ 10^{-3}\ \text{dpm yr}^{-1}$) [used to estimate diffusion of ^{238}U] are essentially consistent with a model which depicts a steady state distribution of uranium in the ocean."

Passive adsorption and electrochemical processes are presently the two different methods to extract elements and minerals directly from seawater. Seawater contains large amounts of valuable minerals including 17 REEs, precious metals, lithium, and uranium.

Whereas land-based minerals are concentrated in specific geologic formations, seawater minerals are distributed evenly in seawater, although higher concentrations can occur near continents as a result of runoff from the crustal rocks from which these elements come. Extracting minerals from seawater is more environmentally-friendly than mining on land as it does not require fresh water or create volumes of contaminated water and mining tailings.

The most economical methods use passive adsorption technology, thereby avoiding the energy needed to process or pump large volumes of seawater. In a passive extraction system, the natural ocean currents deliver seawater to the adsorbent for extraction of the elements of interest. Passive systems are envisioned as farms resembling a kelp forest that are planted and harvested like crops (Fig. 3). Fig. 4 shows the retrieval of one harvested acrylic fiber sorbent from an ocean demonstration.

The latest technologies for extracting U from seawater build on work by researchers in Japan and use polyethylene fibers coated with various amine compounds (Fig. 5), such as amidoxime, to pull in and bind uranium dioxide from seawater (Fig. 6). In seawater, amidoxime attracts and binds uranium dioxide to the surface of the fiber braids, which can be on the order of 15 cm in diameter and run multiple meters in length depending on where they are deployed.

After a month or so in seawater, the length of braided fibers are remotely released to the surface and collected. An acid treatment recovers the uranium in the form of a uranyl complex, regenerating the fibers that can be reused many times. The concentrated uranyl complex then can be enriched to become nuclear fuel.

Another method has been researched by Haji and co-workers. Haji et al. (2017a,b) built on the previous systems described by Picard et al. (2014) and Haji and Slocum (2016) to design a mechanical exposure system they call Symbiotic Machine for Ocean uRanium Extraction (SMORE) that uses adsorbent shells that are incrementally spaced along a continuous moving roller chain that washes the sorbent with fresh seawater (Fig. 7). The energy needed to operate these systems depends on the type of material and approaches used. Absorbents can be electrochemically enhanced for better sorption and desorption, or just mechanically driven by belts or roller chains into and out of the seawater and into and out of extraction baths.

This procedure, along with the global effort, involves synthesizing and characterizing uranium adsorbents and marine testing of these adsorbents at facilities like PNNL's Marine Sciences Laboratory in Sequim, Washington (Alexandratos and Kung, 2016; LiVecchi et al., 2019). In addition to marine testing, PNNL assessed how well the adsorbent attracted uranium versus other elements, how durable the adsorbent was, how buildup of marine organisms might impact performance, and which adsorbent materials are not toxic (Gill et al., 2016).

This marine testing shows that these new fibers have the capacity to hold at least 6 g of uranium per kilogram of adsorbent after only about 50 days in natural seawater. A video of U extraction from seawater can be seen on the University of Tennessee Knoxville website.

The first uranium yellowcake extracted from seawater by the United States occurred in 2018 during 3 month-long tests at the Sequim facility. It used inexpensive sorption-coated acrylic fibers developed by an Idaho-based clean energy company LCW

Fig. 3 Scientists envision anchoring hundreds of lengths of U-extracting fibers in the sea for a month or so until they fill with uranium. Then a wireless signal would release them to float to the surface where the uranium could be recovered and the fibers reused. Fiber length can be up to 60 m, a chain over a kilometer-long set on the sea floor up to 200 m below the surface with at least 40 m of seawater above the top of the fibers. It doesn't matter where in the world the fibers are floating. Courtesy Oak Ridge National Laboratory.

Supercritical Technologies with early support from PNNL through DOE's Office of Nuclear Energy. Seawater was pumped through about a kilogram of fiber and the uranium was then extracted, producing about 5 g of uranium. Calculations indicate this method would be cost-compatible with mining if scaled up.

Of course, other elements can be extracted from seawater as well, either by the same process or others acting simultaneously. **Fig. 8** shows the relative abundance of elements extracted by the amidoxime-based sorbents from ORNL.

When nuclear becomes renewable

Because uranium extracted from seawater is replenished continuously from the Earth's crust in a thermodynamically-controlled steady-state ([Ku et al., 1977](#)), it will be theoretically impossible to drop the amount of U in seawater significantly even as you're extracting it. Therefore, nuclear energy effectively can become as endless as solar and wind.

However, seawater concentrations of uranium are controlled by steady-state, or pseudo-equilibrium, chemical reactions between waters and rocks on the Earth, where it is transported by rivers to the ocean. Although mixing rates and equilibria reaction rates are generally unknown, extrapolations from how other elements are replenished by dissolution of crustal rocks suggest they are fast enough to keep seawater U concentrations about the same no matter our rate of removal ([Ku et al., 1977](#)).

Fig. 4 Uranium acrylic fiber sorbent deployment and retrieval by Texas A&M University at Galveston researchers. Courtesy Chen Xu.

Fig. 5 Researchers around the world have been working frantically to develop an array of materials and fibers able to economically extract uranium from seawater. They have succeeded, as discussed at a conference devoted to the topic. Courtesy Oak Ridge National Laboratory.

Crustal rocks contain 100 trillion tons of uranium ([LiVecchi et al., 2019](#)). Whenever uranium is extracted from seawater, more is leached from crustal rocks to replace it. So it is unreasonable to think that humans could extract enough uranium to significantly lower the overall seawater concentrations of uranium over the next billion years, even if nuclear provided 100% of our energy and our species lasted a billion years.

Fig. 6 Researchers at the Pacific Northwest National Laboratory exposed this special uranium-sorbing fiber developed at ORNL to *Pseudomonas fluorescens* and used the Advanced Photon Source at Argonne National Laboratory to create a 3-D X-ray microtomograph to determine microstructure and the effects of interactions with organisms and seawater. (C and D) Side and top views of a SMORE 1:10 physical scale adsorbent ball-chain ladder which uses rollers to move the ball-chain lengths of adsorbent through the water column (Haji et al., 2017a). Courtesy American Nuclear Society.

In other words, uranium in seawater is renewable. Possibly as renewable as solar energy. Yes, uranium in the crust is, strictly speaking, finite. But so is the Sun, which will eventually burn out. But that won't begin to happen for another 5 billion years. Even the wind on Earth will stop at about that time as our atmosphere boils off during the Sun's initial death throes as a Red Giant.

Cost

Anecdotally, observers note that alternatives to the current means of mining uranium ore would help, and are possibly necessary for, the future of nuclear energy. Advances by PNNL and ORNL have reduced the cost of seawater uranium extraction

Fig. 8 Relative abundance of elements absorbed by the ORNL AF1 adsorbent after 56-day seawater exposure in a column flow-through system: (A) by mass percentage; (B) by molar percentage. The insets are the expanded view for Ni, Ti, Sr, Co, Cr, and Mn. Courtesy U.S. Pacific Northwest Laboratory.

by a factor of four in just 5 years. But at more than \$200/lb. of U_3O_8 , the cost remains twice as much as needed to replace mining uranium ore.

The cost of uranium is a small percentage of the cost of nuclear fuel, which is itself a small percentage of the cost of nuclear power. Over the last 20 years, uranium spot prices have varied between \$22 and \$267/kg (\$10 and \$120/lb) of U_3O_8 (Fig. 9), mainly from changes in the availability of weapons-grade uranium to blend down to make reactor fuel, followed by the shutting of Japan's nuclear fleet after Fukushima, and now from changes in energy use during the coronavirus pandemic (Fig. 10).

So, as the cost of extracting U from seawater falls to below \$225/kg (\$100/lb), it will become a commercially viable alternative to mining new uranium ore. But even at \$450/kg (\$200/lb) of U_3O_8 , the addition to the cost of nuclear power is no more than a fraction of a cent per kWh (World Nuclear Association, 2008). Research by Dr. Haji at Cornell indicates that the economics are even better if the mineral harvester shares its infrastructure with another offshore system such as a wind turbine or oil platform.

Fig. 9 Historical Spot Price of Uranium from 1988 to 2019 in US\$/lb. of U_3O_8 . As of late April, 2019, the price remains between \$25.00 to \$30.00 as a result of long-term uranium oversupply. But Japanese re-starts with Chinese and other new reactor start-ups will diminish the oversupply and catalyze a rise in uranium spot prices over the next decade. Before 2006, spot prices remained very low as cheap weapons-grade U was blended down to make commercial fuel. Spot prices are per pound of yellowcake (upper right) that is processed from uranium ore rock (upper left).

Fig. 10 Uranium spot prices over the last year, noting the big surge in price after the pandemic began, from about \$25/lb to \$34/lb. These are still quite low compared to the over \$100/lb prices from about 10 years ago after cheap weapons stocks of U had been exhausted. Spot prices are per pound of yellowcake (upper right) that is processed from uranium ore rock (upper left).

Conclusion

Extraction of uranium from seawater has become viable technically and should become viable economically within a relatively short time. The leading methods use passive adsorption technology, where the natural ocean currents deliver seawater to an adsorbent, particularly amidoxime-coated polyethylene fibers. Passive systems are envisioned as farms resembling a kelp forest that are planted and harvested like crops.

Importantly, nuclear fuel made with uranium extracted from seawater makes nuclear power completely renewable. According to Professor Jason Donev from the University of Calgary, “Renewable literally means “to make new again”” (Donev, 2020). Any resource that naturally replenishes with time, like the creation of wind or the growth of biological organisms for biofuels, is certainly renewable. Renewable energy means that the energy humans extract from nature will generally replace itself. And now uranium as fuel meets this definition.”

Nothing is renewable forever. All humans need are sources that are *practically* renewable for as long as humans exist.

So, for all practical purposes, solar, wind, hydro and nuclear are all renewable.

Introduction

Phosphate rock or phosphorites are minerals that contain phosphorus (P), measured by its phosphorus pentoxide (P_2O_5) content at elevated concentrations. In phosphate ore the concentrations of P_2O_5 usually range from 5–25%. To be marketed the P_2O_5 is concentrated to roughly 30%. Simple screening and more elaborate techniques such as flotation and calcination are used for the concentration or beneficiation of P_2O_5 . P is an essential building block for plants and animals. To feed the world approximately 250 million t of phosphate rock are mined annually. This makes phosphate rock the fourth most mined material on earth. The majority (>90%) of the mined phosphate rock is used for mineral fertilizer production. As of now there is no substitute for P in fertilizer production and large-scale recycling of P is still in its infancy. Phosphate rock is thus directly tied to food security.

Phosphate rock can contain a number of accompanying valuable elements in elevated concentrations that could justify commercial recovery (depending on specific market conditions and production costs). Most notably, rare earth elements (REE) and uranium could be industrially recovered (Chen and Graedel, 2015). Uranium can be found in some phosphate rock in relevant average concentrations of 70–200 mg/kg that could justify recovering it. Uranium is a relatively common element in the earth crust appearing with an average concentration of 2.8 mg/kg. In comparison, the average concentration of uranium in seawater that is, as a result of the tremendous overall quantities of uranium (approximately 4 billion t), often considered as a future uranium resource is as low as 0.003 mg/kg or 3 parts per billion. Uranium resources can be differentiated by concentration (WNA, 2020a,b) into very high-grade ores, high-grade ores, low-grade ores and very low-grade ores as indicated in Table 1.

Average uranium concentrations in phosphate rock deposits in Algeria (Djebel Kouif, 100 mg/kg), Angola (Cabinda, 260 mg/kg), Brazil (Araxa, 182 mg/kg and Catalao, 220 mg/kg), Burkina Faso (Kodjari, 125 mg/kg), Egypt (Hamrawein, 110 mg/kg, Safaga, 120 mg/kg, and West Mahamid, 100 mg/kg), Israel (Arad, 150 mg/kg), Mali (Tilemsi, 123 mg/kg), Morocco (undifferentiated, 130 mg/kg), Tanzania (Minjingu, 390 mg/kg), United States (Central Florida, 141 mg/kg and Idaho, 107 mg/kg) as reported by Van Kauwenbergh (1997) could thus also be classified as very low-grade uranium ores.

Ironically, several phosphate rock producers mine ores with natural uranium concentrations exceeding those of commercial uranium mines. Uranium from phosphate is considered an unconventional resource, since mining phosphate rock for its uranium content alone or recovering uranium as a by-product is presently considered uneconomic. Should uranium prices increase, or technologies allow for more cost-effective recovery, uranium from phosphates could become a conventional uranium resource again.

It is noteworthy that radiotoxic uranium from phosphate rock, not recovered during phosphate fertilizer production will largely transfer to the final fertilizer product and ultimately be distributed on agricultural soils. There is an active scientific discussion regarding the potential harm of uranium brought out with mineral fertilizers on agricultural soils (Bigalke et al., 2017; Liesch et al., 2015; Schnug and Haneklaus, 2015). While there is presently no legal limit for uranium in fertilizers, the German Commission for the Protection of Soils for instance, proposed setting it to 50 mg uranium per kg P_2O_5 (Kratz et al., 2016) or 167 mg uranium per kg fertilizer with a P_2O_5 content of wt30%.

Past uranium recovery from phosphates

Phosphate rock is present as apatite, most commonly fluorapatite ($Ca_5(PO_4)_3F$ or $Ca_{10}(PO_4)_6(F,OH)_2$), that is soluble on only very acidic soils as they are found in some tropical areas. To make P accessible to plants the majority of phosphate rock is processed to soluble mineral fertilizers. The most common process for this is the wet phosphoric acid (WPA) process. During WPA production the concentrated ore is digested with either hydrochloric acid (HCl) (Eq. 1), nitric acid (HNO_3) (Eq. 2) or sulfuric acid ($H_2SO_4 \cdot nH_2O$) (Eq. 3).

Table 1 Uranium resources by concentration.

Classification	Uranium concentration	
Very high-grade ore	20%	200,000 mg/kg
High-grade ore	2%	20,000 mg/kg
Low-grade ore	0.1%	1000 mg/kg
Very low-grade ore	0.01%	100 mg/kg

WNA (World Nuclear Association) (2020a) *Supply of Uranium*. <https://www.world-nuclear.org/information-library/nuclear-fuel-cycle/uranium-resources/supply-of-uranium.aspx>.

**Fig. 1** Schematic overview of the wet phosphoric acid (WPA) process with uranium recovery.

Phosphate rock digestion with sulfuric acid is the most common process, used in about 75% of the roughly 400 fertilizer plants operating worldwide. The use of sulfuric acid is attractive from an industrial viewpoint as calcium is simultaneously precipitated as solid calcium sulfate known as phosphogypsum ($\text{CaSO}_4 \cdot n\text{H}_2\text{O}$) that can be separated using simple filtration. The use of hydrochloric acid and nitric acid do in contrast form water-soluble calcium nitrate ($\text{Ca}(\text{NO}_3)_2$) or calcium chloride (CaCl_2) that require more costly purification techniques. Besides, the majority (80–90%) of the radiotoxic radium transfers to the phosphogypsum replacing Ca in the chemical structure if sulfuric acid is used instead of being liberated as is the case with hydrochloric- and nitric acid digestion. Depending on the crystallization temperature, gypsum dihydrate ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), hemihydrate gypsum ($\text{CaSO}_4 \cdot 0.5\text{H}_2\text{O}$) and gypsum anhydrite (CaSO_4) that are usually all referred to as phosphogypsum are produced. For every 1 t phosphoric acid approximately 5 t phosphogypsum (dry weight) are produced. As a result of its low radioactivity most of the produced phosphogypsum (100–280 million t/year) is stacked next to fertilizer plants and not further processed (Saadaoui et al., 2017; Tayibi et al., 2009). Even the relatively low radioactivity concentrations (0.2–3 Bq/g for ^{226}Ra) present in most phosphogypsum does not permit further using it under most national regulations today. Recent successful case studies on the use of phosphogypsum as construction material and soil amendment are slowly changing the practice of stacking (Hilton et al., 2020). Reducing the radioactivity even further by removing radium decay products could make this phosphogypsum available as an inexpensive resource for agriculture and construction. The WPA process for fertilizer production with uranium recovery is schematically shown in Fig. 1.

After the phosphogypsum is filtered out uranium can be recovered from phosphoric acid. Phosphoric acid must be purified in the WPA process depending on its further use, as other impurities in addition to uranium such as iron, magnesium, arsenic, aluminum, etc. are dissolved in the digestion stage and transfer into the phosphoric acid. Food and pharmaceutical industries require high-grade phosphoric acid whereas low-grade phosphoric acid is sufficient for fertilizer production.

While the majority (60–90%) of the uranium transfers into the phosphoric acid stream the majority of the REEs will be found in the phosphogypsum, making recovery of the REEs more challenging. For uranium recovery from phosphoric acid, mostly solvent extraction (SX) and to a much lesser extent ion exchange (IX) techniques were used in the past (Haneklaus et al., 2017a). Particularly, solvent extraction of uranium from phosphoric acid can be considered an industrially mature technology that has also been reviewed in the scientific literature (Beltrami et al., 2014; Bunus, 2000; Singh et al., 2016) while new ion exchange processes are currently investigated for future uranium recovery from phosphates that will still need to be tested on industrial scale.

Besides, it is also possible to leach uranium directly from phosphate rock using weak acids and conventional leaching techniques (Al-Khaleedi et al., 2019). Lab-scale experiments that leached uranium and REE from phosphate rock showed that such an approach can be beneficial in a way that uranium is removed early on in the process and at least the radioactivity in phosphogypsum caused by ^{238}U can be dramatically reduced.

Assuming uranium recovery from WPA, the amount of uranium that can be recovered from a certain phosphate rock can be estimated using Eq. (4) for phosphate rock and Eq. (5) if mass and uranium concentrations of the relevant phosphoric acid are provided.

$$m_U = (m_{PR} * c_{U,PR} * f_{U,PA}) * \eta_{U,PA} \quad (4)$$

$$m_U = (m_{PA} * c_{U,PA}) * \eta_{U,PA} \quad (5)$$

m_U = Mass uranium, m_{PR} = Mass phosphate rock, m_{PA} = Mass phosphoric acid, $c_{U,PR}$ = Concentration of uranium in phosphate rock, $c_{U,PA}$ = Concentration of uranium in phosphoric acid, $f_{U,PA}$ = Fraction of uranium that transfers from the phosphate rock to the phosphoric acid, $\eta_{U,PA}$ = Extraction efficiency of uranium from phosphoric acid.

The amount of uranium that could thus be recovered from 1 t phosphate rock from Central Florida (m_{PR}) that shows an average uranium concentration ($c_{U,PR}$) of 141 mg/kg (Van Kauwenbergh, 1997), if 80% ($f_{U,PA}$) of the uranium transfers to the phosphoric acid and 90% ($\eta_{U,PA}$) can be extracted from the phosphoric acid is a bit more than the mass of a chocolate bar or 102 g.

Larger phosphate fertilizer plants process 500,000 thousand to 2 million t phosphate rock per year resulting in notable potential for uranium recovery. Table 2 summarizes past commercial uranium recovery activities in the United States, Belgium, Canada, Taiwan and Iraq. Different extractant solvents were used for uranium recovery that gave the respective process its name. Bis(2-ethylhexyl) phosphoric acid (DEPA) and tri-n-octylphosphine oxide (TOPO) was the most popular extractant used for the DEPA-TOPO or ORNL process named after Oak Ridge National Laboratory (ORNL) in the United States where the process was developed.

Uranium recovery activities are sometimes classified in a 1st and 2nd wave of uranium recovery from phosphates (Haneklaus et al., 2015a). In the 1st wave (1951–61) uranium mining was still in its infancy and various materials, including phosphate rock, were considered to be potential sources of uranium. With the discovery of higher-grade uranium deposits the 1st wave and uranium recovery from phosphates stopped. The 2nd wave (1976–98) was commercially driven. Since the majority of costs for excavation, mining infrastructure, etc. are covered by the phosphate industry already (Reitsma et al., 2018) and uranium prices were favorably high as a result of the oil crisis in 1973, operating commercial uranium extraction plants next to fertilizer plants was economic for some time and done in the United States, Belgium, Canada, Taiwan and Iraq. In addition, uranium was recovered from phosphates in Kazakhstan behind the iron curtain, and many other countries operated pilot plants investigating potential uranium recovery from domestically mined or imported phosphate rock.

Particularly impressive was uranium recovery from phosphates in the United States, where the technology at its height contributed up to 20% of the domestic uranium production in the 1980s before decreasing uranium prices made this process uneconomic. Fig. 2 compares historic uranium imports and historic uranium mining with historic and potential uranium recovery from phosphates in the United States.

Like many other countries that rely on nuclear power for a considerable share of their electricity production the United States is importing the bulk of the required uranium from abroad. Interestingly, since the 1990s the amount of uranium that could theoretically be recovered from phosphates as a byproduct in fertilizer production could be larger than actual domestic uranium mining. In this context, recent concerns about uranium supply security in the US may indeed *make uranium recovery from phosphates great again* as speculated by Steiner et al. (2020).

Table 2 Historic uranium recovery from phosphates by country and plant.

Operating period	Country	Plant	Uranium extraction process	Capacity (t U/year)
1951–62	United States	Joliet, IL	Precipitation	31
1952–56	United States	Texas City, TX	OPPA	20
1954–59	United States	Nichols, FL	–	–

Fig. 2 Historic US uranium imports, uranium mining, past- and potential uranium recovery from phosphates.

Potential uranium recovery from phosphates

The potential of uranium from phosphates can be estimated using annual production data and phosphate rock reserves as they are published annually by the [USGS \(2020\)](#) as well as average concentrations of uranium in these phosphates. [Table 3](#) shows the amounts associated with phosphate rock of the largest 23 producing countries in 2018 as well as the quantity of uranium associated with phosphate rock reserves in these countries. Production data was taken from the [USGS \(2020\)](#) and average uranium concentrations by country were taken from [Van Kauwenbergh \(1997\)](#).

The very simple quantitative assessment in [Table 3](#) indicates that there are roughly 14,000 t uranium associated with phosphate rock production annually. Of these 14,000 t approximately 8800 t of uranium are associated with phosphate rock that show elevated concentrations of 90 mg uranium per kg that may justify economic recovery. The brief estimate presented here corresponds well to more elaborate studies by [Gabriel et al. \(2013a,b\)](#) and [Ulrich et al. \(2014\)](#) that estimate the potential uranium from phosphate rock to be as high as 10,000 t and 11,000 t respectively.

In this context, world uranium production for the same year (2018) was approximately 53,000 t ([WNA, 2020b](#)). Equally impressive are the total amounts of uranium associated with phosphate reserves that are with 6.25 million t as high as recoverable identified uranium resources (6.15 million t) ([WNA, 2020b](#)). Just like the amount of uranium associated with seawater, the quantity of uranium from phosphates is impressive, but will only be relevant if it can be recovered economically.

The economics of phosphate production, the uranium price and environmental benefits of recovering uranium are the most important factors to determine whether uranium recovery from phosphates is economic or not ([Haneklaus et al., 2017b](#)). In addition, strategic considerations such as uranium supply security may be considered.

To estimate quantities of uranium that may be recovered economically one day a cut-off grade of 90 mg uranium per kg phosphate rock is often used. [Kim et al. \(2016\)](#) and [Steiner et al. \(2020\)](#) estimated that the quantities of unconventional uranium that could be recovered during phosphate rock processing in the United States could theoretically cover 10% of the national uranium requirements (2116 t of 20,386 t uranium in 2014). Similar assessments were conducted by [Shang et al. \(2021\)](#) for China, indicating that China could have recovered some 648 t uranium during phosphate fertilizer production in 2016. This amount could have covered nearly 10% of the country's reported uranium requirements for that year. The Chinese case study is particularly interesting since the average uranium content in Chinese phosphate rock (27 mg/kg) provided by [Van Kauwenbergh \(1997\)](#) in [Table 3](#) would not justify uranium recovery. More recent investigations by [Ye et al. \(2019\)](#) found that there are indeed phosphate rock locations in China with uranium concentrations as high as 480 mg/kg. Even if these deposits are not in the majority, uranium recovery from them should be considered and could add relevant amounts of heavy metal to the country's uranium supply.

The Chinese case study is further relevant as it highlights the importance of relatively small deposits with elevated uranium contents that could actually profit from recovery of most uranium from those phosphates and could be the next locations where this technology may be relevant. Another example of this is the Minjingu phosphate rock deposit in Tanzania that shows elevated average uranium concentrations of 390 mg/kg with peak concentrations reaching nearly 800 mg/kg. The high uranium (and also REE) concentrations of the Minjingu deposit may justify multi-element mining as is already done at Olympic Dam in Australia.

Besides the case studies for the United States and China, [Tulsidas et al. \(2019\)](#) and [López et al. \(2019\)](#) conducted case studies for the European Union where 2% of the uranium requirements or 334 t uranium of 16,084 t total demand could have come from

phosphates in 2017 and Argentina where 8% of the uranium requirements or 19 t uranium of 235 t uranium could have come from phosphates in 2017. Both case studies assume a cut-off grade of 90 mg/kg, and in both case studies phosphate rock imports are of significant importance.

All countries need phosphate fertilizer for their food production and several countries have phosphate rock processing facilities without actually mining phosphate rock. Detailed material flows are for instance available for a phosphate rock processing plant in the Philippines [Haneklaus et al. \(2015b\)](#) that processes phosphate rock from different parts of the world.

Morocco has by far the largest phosphate rock reserves in the world (73% in [Table 3](#)) and this phosphate rock shows elevated uranium concentrations of 97 mg/kg that are often reported to actually be as high as 130–160 mg/kg ([Azouazi et al., 2001](#)). Orano SA (previously Areva SA), the large multinational nuclear fuel cycle company headquartered in France, signed a memorandum of understanding with Morocco's state-owned phosphate rock mining company (OCP Group) in 2006 for uranium recovery from Moroccan phosphates. Unlike the United States and China that are the other major phosphate rock producing countries in the world (see [Table 3](#)), Morocco does not have a large national market for phosphates and exports most of the mined ore to other countries.

Given the current phosphate rock reserves, Morocco will most likely supply various regions in the world with phosphate rock, phosphoric acid and phosphate fertilizers in the near future ([Cooper et al., 2011](#)). The increased use of Morocco phosphate rock with elevated uranium concentration could favor uranium recovery. Mineral resources are dynamic in a way that innovations and exploration efforts continuously discover “new” materials deemed economic for mining and processing ([Scholz and Wellmer, 2013](#)). Seabed phosphates, such as the Chatham Rise deposit offshore of New Zealand with 240 mg/kg uranium content may become a resource soon, changing the current assumptions about resources, reserves and geological potential one more time.

While one day phosphate rock may be mined not only for its P content but for all its constituents such as uranium, REE and its rock matrix that can be used in construction after radiotoxic uranium and its radioactive decay daughters have been recovered ([Zhang, 2014](#)), this is clearly not the case yet. The latest push towards commercial uranium recovery from phosphates by PhosEnergy was put on hold in 2019 as a result of low uranium prices. These low uranium prices are presently forcing some commercial uranium mines into a state of permanent maintenance. Facilities to recover uranium from phosphates can be erected fairly quickly (2–3 years) compared to the time required to set-up a new commercial uranium mine (5–10 years). Should uranium prices rise again though, it will most likely be uranium mines currently shut down that will be online first to fill the demand gap.

Conclusions and outlook

Quantities and concentrations of uranium associated with phosphates are considerable, and uranium from phosphates is probably the most important unconventional uranium resource that is not mined today. Although the majority of the costs for excavation, infrastructure development, mining, and processing are covered by the phosphate industry, uranium recovery from phosphates is not profitable today and it is unlikely that this will change as long as uranium prizes are low. However, uranium supply security and environmental concerns may lead to uranium recovery from phosphates at selected locations.

Introduction

After mining, milling, and associated chemical processing, the resulting product usually consists of a dry powder that is still impure but concentrated in uranium oxides, especially U_3O_8 or UO_3 (Hausen, 1998). This material is neither chemically nor isotopically suited for direct use in nuclear fuel material and is instead subjected to subsequent chemical processing referred to as conversion. This process purifies the incoming concentrates but also, as the name implies, chemically converts the concentrates into the form required by the subsequent processing step, which is most typically an enrichment process requiring uranium hexafluoride, UF_6 . The term is occasionally used to include the direct conversion of concentrates to UO_2 , such as for CANDU reactors, essentially skipping an enrichment step in the nuclear fuel cycle, however conversion to UF_6 is the far more predominant process. A small number of large facilities provide all the conversion services for the world's nuclear energy industry, with only three facilities supplying 93% of global demand in 2019.

After conversion, the isotopic composition of uranium is too low to use as fuel for most types of nuclear reactors. The fissile isotope, ^{235}U , makes up only 0.71% of all naturally occurring uranium, with the balance consisting almost entirely of the non-fissile isotope ^{238}U . While ^{238}U is fertile and some fuel cycles, such as that used by the previously-mentioned CANDU reactors, can use uranium with this naturally occurring isotopic composition (called "natural uranium"), most reactors require a higher concentration of ^{235}U to perform as designed or even to achieve criticality at all. The process of increasing the concentration of ^{235}U in uranium is called enrichment.

However, achieving this increase is notoriously technically demanding. As is the case with all isotopes of a single element, ^{235}U and ^{238}U have nearly identical chemical and physical properties, thus viable enrichment processes are limiting to exploiting the mass difference between the target isotopes, a requirement made even more difficult by the fact that the two uranium isotopes of interest exhibit a mass difference of only just over 1%.

The technical challenges are further complicated by the nuclear weapons proliferation concerns associated with uranium enrichment. Although enriching uranium to 3–5% ^{235}U yields material sufficient to fuel nearly all the world's nuclear energy generation capacity, the same enrichment technologies can yield even higher enrichments, up to the 90% or more typical of a nuclear weapon. Few technological barriers exist to developing a rudimentary but powerful nuclear weapon once enough uranium of sufficient enriched is obtained, and for that reason uranium enrichment technology is closely controlled by the nations that deploy it, classified among the most closely guarded national security secrets any nation possesses.

These aspects combine to make uranium enrichment technology uniquely difficult to develop and expensive to deploy. Nevertheless, the drive for ever-improving enrichment technologies continues because the unique challenges are only exceeded by the unique properties of enriched uranium and the essential role it plays in the global nuclear energy industry.

Conversion processes

The process of uranium conversion adapts a variety of well-established chemical processing technologies and is now a mature manufacturing industry benefitting from decades of optimization focused on every detail of the process. The process itself must yield a high purity product with a uniform chemical and physical form as dictated by their customer, generally conforming to a standard such as ASTM C996-20. While any number of chemical processes are potentially suitable, the current industry has settled on a chemical processing route known as the "wet" process. U.S. general partnership ConverDyn employs an alternative "dry" process, however that conversion facility ceased production in 2018 with restart planned for 2023 at the earliest.

The wet process starts with dissolving the incoming uranium concentrates in nitric acid, yielding a yellow-colored solution of uranyl nitrate, $\text{UO}_2(\text{NO}_3)_2$. An organic solvent extraction process is then utilized, which may vary slightly between facilities but nonetheless produces a precipitant that is then dried into a purified uranyl hexahydrate, $\text{UO}_2(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ and thermally decomposed to yield uranium trioxide, UO_3 (Cameco, 2021). The UO_3 is then processed in a furnace or kiln and reacted with hydrogen gas to reduce the contents to uranium dioxide, UO_2 . At this point, the product may be further processed to UF_6 for subsequent enrichment or used as-is if no enrichment is required. To convert to UF_6 , solid uranium tetrafluoride (UF_4) is first produced via the reaction $\text{UO}_2 + 4\text{HF} \rightarrow \text{UF}_4 + 2\text{H}_2\text{O}$, which occur with aqueous hydrofluoric acid (HF) in solution, or completely in the gas phase. Finally, gaseous fluorine (F_2) is reacted with the UF_4 , generally in a fluidized bed reactor, to produce the UF_6 final product, which is then condensed and stored in purpose-built containers for shipment to the customer.

The dry process forgoes the dissolution, solvent extraction, and drying steps and directly reduces the incoming oxide uranium concentrate with hydrogen in a furnace to produce UO_2 , which is then subject to the same process described above to yield UF_6 . Although this produce does not realize the purification benefits of the solvent extraction steps of the wet method, purification is instead realized by distilling the UF_6 , drawing off light fraction gases and impurities and leaving UF_6 of over 99.99% purity (ConverDyn, 2020).

Enrichment process overview

While enrichment processes vary, they share some fundamental commonalities. All modern commercial enrichment processes use natural UF_6 as the input (“feed”) and yield enriched UF_6 as the product. The target enrichment depends upon the application; however the vast majority of modern enrichment operations are aimed at civilian nuclear energy generation and yield product in the 3–5% range. Higher enrichments are used in smaller quantities, frequently up to 20%, the upper limit that can be considered Low Enriched Uranium (LEU). Enrichments above 5% but less than 20% are often referred to as High Assay, Low Enriched Uranium or HALEU, and are of growing interest beyond research reactors for advanced reactors intended for widespread deployment. Beyond 20% enrichment is considered High Enriched Uranium, or HEU, and used for a small number of research reactors as well as many naval reactors and for nuclear weapons.

In addition to the product, the enrichment process necessarily produces another output stream consisting of UF_6 depleted in ^{235}U , called “tails.” These three quantities and their respective ^{235}U to U ratios (called assays) are related by a series of two equations consisting of the feed to product ratio,

$$\frac{F}{P} = \frac{x_p - x_t}{x_f - x_t}$$

and the tails to product ratio,

$$\frac{T}{P} = \frac{x_p - x_f}{x_f - x_t}$$

Where F, P, and T are the feed, product, and tails masses, respectively; and x_f , x_p , and x_t are the respective assay of the feed, product and tails. These equations illustrate several important considerations in enrichment, but one that stands out is that a low tails assay is required to yield the greatest product quantity while minimizing the use of feed. The amount of feed is an important economic driver for enrichment processes because its mining, milling, and conversion represent a substantial expense. However, enrichment processes are not perfectly efficient and, in practice, the UF_6 can pass through as many as thousands of individual enrichment stages to reach the desired enrichment. The work required to achieve product assay x_p is quantified as separative work units, or SWU, and defined as

$$\text{SWU} = P \cdot V(x_p) + T \cdot V(x_t) - F \cdot V(x_f)$$

where the value function is, in turn, defined as

$$V(x) = (2x - 1) \ln\left(\frac{x}{1-x}\right)$$

These constraints define a balance between the work required for enrichment and the resources required to produce the feed material, and any calculation of an optimum set of parameters incorporates these constraints. Typically, tails assays are in the range of 0.2–0.4% ^{235}U , and the product is enriched to 3–5% for light water reactors (LWRs), meaning that only approximately 10% of the feed is converted into product, with the remaining 90% resulting in tails with limited or no economic utility. These tails are often referred to as “depleted uranium,” or DU, because the tails are depleted in the ^{235}U isotope. While DU does have some useful applications, these demands are dwarfed by DU production as a byproduct of enrichment. A modern, large LWR requires on the order of 100,000 kgSWU/year, and the large enrichment plants responsible for most of the world's SWU produce on the order several million kgSWU/year.

These costs constitute a significant driver of the economics of nuclear plant operations and are governed by a complex set of supply and demand relationships between mining, milling, conversion, enrichment, fuel fabrication, and power generation. These market-driven costs may fluctuate substantially over a period of years, with enrichment at times making up most of the total cost of

fuel production. Although fuel makes up only approximately 20% of the overall cost of nuclear power (Nuclear Energy Institute, 2020), enrichment costs are still significant in a nuclear power industry with tight profit margins, where \$0.01/kWh can make a meaningful difference in decisions to retire legacy plants, or in financing new reactor builds.

Enrichment technologies

Enrichment technologies have followed an evolutionary trajectory that can be traced through historical technology development. While there have been many suggestions for novel techniques, some of which have been demonstrated at laboratory scale, the principal technologies can be divided into a few categories. The earliest enrichment technologies were developed by the United States during World War II as part of the Manhattan Project for the purpose of nuclear weapons. They were enormously expensive but justified by a wartime sense of urgency. Over time, other technologies were developed and improved, until the economics of commercial nuclear energy drove a convergence to a single technology, the centrifuge. Nevertheless, while centrifuges have performed most of the world's enrichment for many decades, the costs and complexity of the technology continue to motivate deployment of a new generation of enrichment technologies as well as evolutionary improvements to the venerable centrifuge.

Electromagnetic

The first practical method for enriching uranium was demonstrated in 1941 using a device called a Calutron. The technique was later improved and deployed on a grand scale in 1943–44 to enrich uranium for the Manhattan Project.

The technique relied upon the mass difference between the different isotopes of uranium, ionizing atoms of metallic uranium (rather than UF_6), accelerating them through an electrical field, then deflecting their trajectory with an orthogonal magnetic field. The lighter ^{235}U atoms experienced greater deflection than did the heavier ^{238}U atoms. A collector specially separated the stream of ions, resulting an enriched product stream accompanied by a depleted tails stream.

The technique was quickly supplanted by the more efficient gaseous diffusion process and the calutrons ceased enriching uranium shortly after the war ended, at a total cost of approximately \$9B in 2020 USD. Electromagnetic separation techniques are no longer used to support the nuclear energy industry, although it remains a concerning route for potential nuclear weapons proliferation (Fig. 1).

Diffusion

The gaseous diffusion technique also was first deployed at a practical scale as part of the Manhattan Project, with the first pilot plant operational in 1944. However, with evolutionary improvements, the gaseous diffusion technique grew into and sustained a role as an important contributor to enrichment capacity, mainly in the United States and France, contributing as much as one third of global production as late as 2008 and continuing in large-scale commercial enrichment operations until 2013. Unlike electromagnetic separation, gaseous diffusion utilizes UF_6 throughout. The technique relies on carefully-engineered barriers through which the UF_6 diffuses. Because the diffusion rate depends on the molecular mass of the gas, lighter molecules diffuse through the barrier at a higher rate, resulting in a slight ^{235}U enrichment of the gas on the lower-pressure side of the barrier. By using large areas of such

Fig. 1 Circa early 1949s diagram of a calutron. Courtesy Westinghouse.

Fig. 2 Georges Besse gaseous diffusion plant after decommissioning. Courtesy Orano.

barriers and rapidly exchanging the gas across them repeatedly (and typically via thousands of stages), this enrichment effect can be multiplied to yield commercially significant throughputs.

However, the operating costs of this technique, particular the electrical demand, is surpassed only by that of electromagnetic separation. The last operational gaseous diffusion plant, located in Paducah, KY in the United States, consumed approximately 3 GW of electricity before it ceased operations in 2013 (Fig. 2).

Thermal diffusion was also deployed during the Manhattan Project at scale and utilized liquid UF_6 to exploit the fact that a thermal gradient yields differential diffusion along the gradient in an otherwise well-mixed solution. However, it was not competitive with gaseous diffusion and the plant was shut down in 1945. The technique has not since been commercially deployed.

Centrifuge

Centrifuge technology is currently the only commercial enrichment process utilized to support the global nuclear energy sector. A centrifuge plant consists of cylinders into which feed UF_6 is flowed. The cylinders are spun at very high speeds, generating large centripetal forces that serve to concentrate the heavier molecules nearer the periphery of the cylinder. The lighter UF_6 , enriched in ^{235}U , is concentrated nearer the center of the centrifuge and can be drawn off to yield a slightly enriched product, while the heavier UF_6 , depleted in ^{235}U , can be drawn off from the periphery of the cylinder. The enriched product stream can then be flowed into a subsequent centrifuge to yield a further enriched product, and the process repeated until the target enrichment is obtained. This system of units that combine small enrichment increments is called a cascade and is ubiquitous in centrifuges and other enrichment technologies.

The performance can be enhanced by reaching higher rotation speeds (either through larger diameters or higher RPM), or employing more modern “Zippe-type” technology that utilizes an axial temperature gradient to increase the efficiency of separation in each stage.

Although simple in principle, the high rotational speeds required for efficient separation require advanced materials, precision machining, and uniquely high-performing components to prevent catastrophic and destructive failure of each centrifuge. Centrifuge performance is varied, distinguished both by the evolution of technology over time as well as the nation deploying it. The technical details of centrifuges are carefully protected by the nations that utilize them (Fig. 3).

A similar but nonetheless unique technique is the vortex process developed in South Africa. In this process, the centripetal forces are achieved not by rotating a cylinder, but by tangentially injecting the gas at high speeds into a carefully designed cylindrical chamber. Though more technically simple than the gas centrifuge process, it is more energy intensive. It was deployed to enrich uranium in South Africa at commercially significant rates, but production was halted when South Africa ended its nuclear program in 1989. Vortex-based enrichment does not currently constitute a significant contribution to global uranium enrichment output.

Laser

Numerous laser techniques for uranium enrichment have been evaluated and tested but are not yet commercially significant. Laser based techniques rely on slightly different spectroscopic properties of the uranium atoms or uranium-based molecules to achieve some spectral selectivity between the isotopes, although the details vary. Molecular Laser Induced Separation (MLIS) was the first technique demonstrated at an engineering scale, investigated in the United States in the 1970s. It used UF_6 gas and selectively excited one isotope with laser radiation until the UF_6 dissociated into UF_5 which precipitated and could be collected. Another technique, Atomic Vapor Laser Induced Separation (AVLIS), was also first developed in the United States and reached closer to commercial deployment. AVLIS used atomic (metallic) uranium as the medium, heated to a vapor. The laser then selectively excited one isotope to ionize it, then the ionized product stream could be collected electrostatically. The technology was developed in the

Fig. 3 Gas centrifuge cascade, Piketon, OH. Courtesy U.S. Department of Energy.

1980s, and eventually was licensed to United States Enrichment Corp. (USEC) in 1994 for eventual commercial operation. However, in 1996 USEC abandoned its pursuit of AVLIS in favor of yet another laser enrichment method called SILEX (Selective Isotope Enrichment by Laser Excitation). Like MLIS, this process also uses UF_6 but has confirmed few technical details. Global Laser Enrichment LLC (GLE) currently controls the technology and continues development with plans to deploy a commercially significant operation in the United States, claiming that their technology can disrupt the industry with reduced deployment cost compared to incumbent technologies.

Downblending

Although the practice does not enrich uranium, in recent years downblending HEU from weapons stockpiles has been an important contributor to SWU needs in the nuclear energy sector. The best known such program has been “Megatons to Megawatts,” an agreement between the United States and Russia to reduce excess Russian HEU inventory originally produced for nuclear weapons. This material was blended with other, low enriched uranium to reduce the enrichment to the level required by nuclear reactor operators, then shipped to the United States to provide enriched uranium for nuclear fuel. Between 1994 and 2013 this agreement resulted in the equivalent of approximately 90 million kgSWU and constituted up to approximately 20% of overall U.S. enrichment demand.

Global production summary

Uranium conversion technology has been widely demonstrated but with the 2018 idling of the U.S. ConverDyn conversion plant due to contracting global demand, only a handful of producers currently supply the world’s needs (see Fig. 4).

Company	Country	Location	Production (2019)
Orano	France	Pierrelatte & Malvési	2500
CNNC	China	Lanzhou & Hengyang	10,000
Cameco	Canada	Port Hope	10,000
Rosatom	Russia	Seversk	12,000
ConverDyn	USA	Metropolis	0
Total			34,500

Fig. 4 2019 Global Conversion Output in metric tons uranium per year (World Nuclear Association, 2019).

Country	Company and plant	2015	2020
France	Areva, Georges Besse I & II	7000	7500
Germany-Netherlands-UK	Urenco: Gronau, Germany; Almelo, Netherlands; Capenhurst, UK.	14,400	14,900
Japan	JNFL, Rokkaasho	75	75
USA	USEC, Piketon	0	0

China	CNNC, Hanzhun & Lanzhou	5760	10,700+
Other	Various: Argentina, Brazil, India, Pakistan, Iran	100	170
Total		58,600	66,700

Fig. 5 Global Enrichment Production in thousands of SWU per year (World Nuclear Association, 2019).

The global enrichment landscape has simplified in recent years as production has shifted essentially entirely to centrifuge technology, although the industry continues to be dynamic, with several large countries accounting for most of the enriched uranium production, while a number of other countries expand their capabilities (see Fig. 5).

In addition, the U.S. company USEC continues to develop and deploy their advanced centrifuge technology and GLE continues to pursue a potentially disruptive generational advancement.

The future enrichment landscape is particularly uncertain given today's growing demand for HALEU. Due to various technical constraints characteristic of uranium enrichment, it is difficult or impossible to convert existing enrichment plants to produce enrichments much beyond 5%. A number of advanced nuclear reactors require nearly 20% enriched uranium, and widespread deployment of such reactors will require new enrichment capacity to be operational well before such reactor deployments in order to produce sufficient fuel.

Introduction

This article presents a summary of fuel performance for fuel pellets made of uranium dioxide or UO₂, uranium-plutonium mixed oxide (MOX) or (U,Pu)O₂, uranium and uranium-plutonium nitrides or UN and (U,Pu)N, and uranium or uranium-plutonium carbides or (U,Pu)_xC_y. All these fuel types have been developed as fuels for sodium-cooled fast reactors, while UO₂ is commonly used in light water and heavy-water reactors as well. The design attributes of these fuel types are presented first. The fuel pellet temperature, which is a function of the pellet radius, the linear heat rate induced by fission, and the cladding and coolant temperature, is a key factor in the fuel performance phenomena, so the approach to analyzing for temperature distribution in a fuel pellet is presented. Fabrication methods are summarized in the latter section of this article.

Fuel design

As the first barrier to hazardous release of fission products and fuel constituents, fuel rods are designed to prevent fuel failure (typically defined as cladding breach). An important design objective and reactor operational requirement is to prevent fuel melting which could allow the fuel to slump axially, with adverse effects on core reactivity, or could cause liquid fuel penetration of the cladding leading to cladding breach. The maximum temperature of the fuel is limited to below the melting temperature of the fuels in early irradiation conditions, usually by limiting the linear heat rate (the power generated per unit length of fuel rod) that can be reached in the fuel rods. Fission products (FPs) accumulate in fuels during irradiation. The accumulation of FPs causes interactions between the fuel and the cladding (termed pellet-cladding interaction, or PCI) including FP gas release, pellet swelling, corrosion of cladding inner walls and so on. In addition, decreases in cladding strength are caused by neutron irradiation damage, which reduces the ability of the cladding to withstand internal pressure and other loads induced during service, possibly leading to fuel failure. It is important to evaluate in the fuel design stage the effects of creep damage of cladding during service. In this section, temperature analysis, pellet properties, and irradiation behavior are summarized, which are all necessary for establishing fuel design.

Temperature analysis in the radial direction of pellets

Power per unit length of fuel rods is called the linear heat rate, represented here by P , and is described with units of W/cm. UO₂ used in light water reactors operates at about 300 W/cm. MOX, nitrides, and carbides used for fuels in sodium-cooled fast reactors operate over 360 W/cm, with maximum values exceeding 400 W/cm.

The linear heat rate L is described by Eq. (1) as a function of thermal conductivity (λ) using the cylindrical coordinate system.

$$L = P/4 \cdot r_1^2 = \lambda(T_0 - T_1) \quad (1)$$

where P is the power per unit fuel volume, r_i is radial direction distance, and T_i is temperature at r_i , as shown in Fig. 1. According to Eq. (1), if we know the temperature dependence of the thermal conductivity of a fuel pellet, we can evaluate the temperature profile in the radial direction. Fig. 1 shows a schematic diagram of temperature profile in the radial direction of a fuel pin. The temperature profile can be described by Eqs. (1)–(4).

$$P = h_G \cdot 2 \cdot \pi \cdot r_1 (T_1 - T_{c1}) \quad (2)$$

Fig. 1 Schematic diagram of temperature profiles in the radial direction of a fuel pin.

$$P = -2 \cdot \pi \cdot \lambda_c (T_{c1} - T_{c2}) \ln \left(\frac{r_{c1}}{r_{c2}} \right) \quad (3)$$

$$P = h_S \cdot 2 \cdot \pi \cdot r_{c2} (T_{c2} - T_{cc}) \quad (4)$$

where λ_c is thermal conductivity of the cladding, h_G is the heat transfer coefficient between the pellet and cladding, called gap conductance, and h_S is heat transfer coefficient between cladding and coolant.

Properties

The physical and thermo-physical properties of fuel materials are essential for evaluating fuel performance in fuel design (Table 1). Crystal structures of the fuel materials are shown in Fig. 2. Oxide fuel has the CaF_2 -type crystal structure, and the other ceramic fuel compounds have the NaCl-type structure. The lattice parameter, a , which is a basic property describing a crystal structure's unit cell is compared in Table 1.

The nitride and carbide fuels have higher density and thermal conductivity than do the oxides. The melting temperature for all materials is about 3000 K. Chemical stability at high temperatures can be a problem for nitrides because the nitride can decompose to metal and nitrogen gas, depending on the nitrogen partial pressure, and this behavior limits the maximum temperature in the fuel design (Uno et al., 2012).

In the stoichiometric composition of oxide fuel compounds, the oxygen-to-metal (O/M) ratio is equal to 2.00, as shown in Fig. 2a; however, oxide fuel is known to be a non-stoichiometric compound stable over wide range of O/M ratio. Specifically, MOX stability expands to hypo-stoichiometric compositions, with O/M ratio lower than 2.00. The stoichiometry significantly affects various properties. Therefore, it is important to understand O/M ratio in property evaluation of MOX fuel.

Morimoto et al. (2008a) measured thermal conductivity of Am-bearing MOX as shown in Fig. 3. The phonon conduction mechanism results in decreased thermal conductivity with increasing temperature. MOX shows slightly lower thermal conductivity than that of UO_2 , and the effect of Am content on thermal conductivity is small. Because the Pu and Am atoms behave as scattering factors in phonon conduction, it is understood that the solid solution of their atoms reduces thermal conductivity. This relationship can be written with the following equation.

Table 1 Property comparison (Carbajo et al., 2001; Solntceva et al., 2016; Sengupta et al., 2012).

Properties	UO_2	MOX ^a	(U,Pu)N ^a	(U,Pu)C ^a

Fig. 3 Thermal conductivity of UO₂ and Am-containing MOX. Morimoto K, Kato M, Ogasawara M, Kashimura M, and Abe T (2008a) Thermal conductivities of (U, Pu, Am)O₂ solid solutions, *Journal of Alloys and Compounds* 452: 54–60.

$$\lambda = (A + BT)^{-1} + \frac{C}{T^2} \cdot \exp\left(-\frac{D}{T}\right) + C \cdot T^3 \quad (5)$$

where, A, B, C, and D are constants. The terms of $(A + BT)^{-1}$, $\frac{C}{T^2} \cdot \exp\left(-\frac{D}{T}\right)$ and $C \cdot T^3$ are phonon conduction, electrical conduction, and radiation contribution, respectively, in Eq. (5). MOX is stable in the hypo-stoichiometric composition. Therefore, thermal conductivity has been investigated as a function of O/M ratio as shown in Fig. 4 (Morimoto et al., 2008b). Decreases in O/M ratio leads to decreased thermal conductivity because oxygen vacancies lead to phonon scattering. Various correlations have been proposed to describe thermal conductivity (Carbajo et al., 2001; Philipponneau, 1992; Kato et al., 2011).

$$\lambda = \frac{(1-p)}{(1+2p)} \left[\frac{1.158 \cdot ((2.85x + 0.035) + (-0.715x + 0.286)T)^{-1}}{\left(\frac{T}{1000}\right)^{\frac{5}{2}}} \cdot \exp\left(-16.35 / \left(\frac{T}{1000}\right)\right) \right] \quad (6)$$

$$\lambda = \frac{1}{0.864} \frac{(1-p)}{(1+2p)} \left[\frac{\left((1.528\sqrt{x + 0.00931} - 0.1055) + (2.885 \cdot 10^{-4} \cdot T)^{-1} \right)}{+76.38 \times 10^{12} \cdot T^3} \right] \quad (7)$$

Fig. 4 Comparison between measured and calculated data of thermal conductivity of $(U_{0.7}Pu_{0.3})O_{2-x}$ with 95% TD.

$$\lambda = \frac{(1-p)}{(1+0.5p)} \left[\frac{(2.713x + 0.3583z_1 + 0.0317z_2 + 0.01595 + (-2.625x + 2.493) \cdot 10^{-4} \cdot T)^{-1}}{+ \frac{1.541 \times 10^{11}}{T^2} \cdot \exp(-1.522 \times 10^4/T)} \right] \quad (8)$$

where x is the substoichiometric deviation in MO_{2-x} , z_1 is Am content, z_2 is Np content in heavy metal, and p is porosity. Values calculated by the equations are shown in Fig. 4 for comparison. Eq. (8) was derived with use of the latest dataset.

Fig. 5 shows the thermal conductivity of nitrides as a function of Pu content. The value increases with increasing temperature and uranium content. Electrical conduction leads to higher temperature dependence of thermal conductivity as compared with oxide fuels.

In Fig. 6, the data are compared for various materials. Thermal conductivity of nitrides and carbides is similar with respect to temperature variation. This relationship in nitrides is described by Ross et al. (1990):

$$\lambda = (1.37 - 1.6C + 1.142C^2) \cdot T^{0.41} \cdot \frac{(1-p)}{(1+2p)} \quad (9)$$

where C is Pu content in $(U + Pu)$.

These correlations describing thermal conductivity are used to evaluate fuel performance using Eq. (1).

Irradiation behavior

Many irradiation tests have been carried out to investigate performance of these fuel types. Microstructure of the cross sections of irradiated pellets are shown in Fig. 7. Cracks are observed in the radial and circumferential directions of the pellets. It can be seen that there is significant restructuring in the irradiated MOX pellet. The MOX pellet in the figure was irradiated at a high linear heat rate of about 420 W/cm, and the high temperature and thermal gradient caused restructuring, which is shown in Fig. 8 (Tanaka et al., 2013). In the radial direction of the pellet, an unchanged region, an equiaxed grain region, a columnar grain region, and a central void are observed (Parrish and Aitkaliyeva, 2018). Pore migration through the fuel pellet plays a major role in restructuring in the radial direction of the pellet. High linear heat rate irradiation tests of minor actinides (MA)-bearing MOX pellets with varying O/M ratio were performed. Larger restructuring was observed in stoichiometric MOX pellets. This O/M dependence of restructuring is significantly affected by the vapor pressure in MOX. Ikusawa et al. (2017) reported that vapor pressure of UO_3 species becomes high in the near-stoichiometric composition, and forms the columnar grain and central void very quickly. The great thermal gradient causes actinide redistribution in the radial direction of the MOX pellet. Pu and Am content increased around the central void as shown in Fig. 9. This compositional change must be considered in fuel design, and the maximum linear heat rate is limited due to the melting temperature decrease caused by enriched Pu in center of the pellet.

An irradiated nitride pellet is shown in Fig. 7c after irradiation at a linear heat rate of about 710 W/cm. However, restructuring in the radial direction, like in the MOX pellet, was not observed because the nitride pellet has a high thermal conductivity and therefore is irradiated at lower temperature.

Many kinds of FPs are generated and accumulated during fissioning. Kleykamp (1985) reported the chemical states of FPs in oxides in detail. The ratio of FPs is different between Pu and U. Fission of Pu or U atoms generate two FPs and two oxygens liberated from molecular MO_2 . FP can be classified into four types according to their chemical behavior as follows:

- Type 1: gases and volatile elements such as Xe, Kr, Br, I.
- Type 2: FPs forming metallic precipitates such as Tc, Pd, Rd, Ru, Ir, Ag.
- Type 3: FPs forming oxide precipitates such as Rb, Cs, Ba, Zr.
- Type 4: FPs dissolved in U and Pu sites such as Nd, La, Ce, Zr.

The behavior of type 1 elements, Xe and Kr, is important in fuel design. Those elements are release as gases from the pellet to the fuel rod plenum (i.e., the empty space inside the fuel rod), increasing the internal fuel rod pressure and PCI. The evaluation of gas release rate is an important factor considered in the fuel design for LWR fuels and fast reactor fuels, because the fuel rod cladding must withstand the pressure of released fission gas. The behavior of FPs in nitrides and carbides is unclear because Post Irradiation Examination (PIE) data is limited.

In oxide fuel, Type 3 and 4 FPs react with liberated oxygen, and some of the surplus oxygen atoms accumulates during irradiation. The O/M ratio increase with burn-up is estimated to be $\text{O/M} = 0.001$ for a burn-up of 10 GWd/t (Matzke, 1995). This means that the chemical potential inside the fuel changes, and the chemical form of FPs, such as Mo and Cs, can change. Oxygen potentials of MOX were investigated by gas equilibrium methods and determined as functions of Pu content, O/M ratio, and temperature, as shown in Fig. 10 (Kato et al., 2017). In the near-stoichiometric region, oxygen potential is drastically changed with O/M ratio.

Fig. 7 Microstructure of the cross section of irradiated fuel pellets: (A) UO_2 pellet irradiated at a maximum linear heat rate of about 320 W/cm; (B) MOX pellet irradiated at a maximum linear heat rate of about 430 W/cm; (C) $(\text{U}_{0.8}\text{Pu}_{0.2})\text{N}$ pellet irradiated at a maximum linear heat rate of about 710 W/cm; (D) $(\text{U}_{0.8}\text{Pu}_{0.2})\text{C}$ irradiated at a maximum linear heat rate of about 450 W/cm. Fig. 9 Redistribution of actinide elements in the radial direction of MOX pellets irradiated in a fast reactor.

Fig. 10 Oxygen potential of $(U_{0.8}Pu_{0.2})O_{2.00 \pm x}$ and $(U_{0.7}Pu_{0.3})O_{2.00 \pm x}$. The oxygen potential of MOX as indicated was measured as functions of temperature, Pu content and O/M ratio. The value increases with increasing temperature, Pu content and O/M ratio. Kato M, Watanabe M, Matsumoto T, Hirooka S, and Akashi M (2017) Oxygen potentials, oxygen diffusion coefficients and defect equilibria of nonstoichiometric $(U,Pu)O_{2 \pm x}$. *Journal of Nuclear Materials* 484: 424–434.

Increased Pu content increases the oxygen potential. Oxygen potential (or the partial molar Gibbs free energy of oxygen in a thermodynamic system), ΔG_{O_2} , is an important thermodynamic property that can be described by the following equation.

$$\Delta G_{O_2} = RT \ln P_{O_2}$$

Here R is the gas constant, T is temperature and P_{O_2} is oxygen partial pressure. The oxygen potential of MOX can be evaluated from O/M ratio, Pu content, and temperature, and then the chemical stability of FPs can be known. Fig. 11 (an Ellingham diagram) shows the temperature and oxygen potential conditions of stability of for oxide compounds of fission products together with the oxygen potential of MOX. The figure which FPs will be stable in MOX as metal and which as oxide; at a given temperature, fission product oxide reactions with values of oxygen potential less negative than that for a MOX compound will be stable in MOX as a metal, while those with oxygen potentials more negative than a MOX compound will be stable as the oxide. For example, the oxygen potentials of $(U_{0.8}Pu_{0.2})O_{2.00}$ and $(U_{0.8}Pu_{0.2})O_{1.97}$ were shown to be about 650 and 400 kJ/mol, respectively, at 1000 K. Therefore, according to the diagram, molybdenum should be stable as MoO_2 and Mo(Metal), respectively, in $(U_{0.8}Pu_{0.2})O_{2.00}$ and $(U_{0.8}Pu_{0.2})O_{1.97}$. This highlights the importance of MOX O/M ratio to the chemical state of fission products, which affects the behavior of those fission products in the fuel.

Fabrication

Fuel fabrication necessarily must produce pellets that meet fuel specification values of pellet density, diameter, appearance, fissile ratio, impurities, and so on, to ensure proper fuel performance. The characteristics of raw material powders and the production process have been improved from conventional methods obtain stable, good pellets (Kato et al., 2020).

Fig. 11 Relative partial molar Gibbs free energies of oxygen of the fission products. The temperature dependence of partial molar Gibbs energies of oxidation reactions in various materials is shown with lines, which is called Ellingham diagram. Chemical stability of FP's can be evaluated by comparison with oxygen potential of oxide fuels (i.e., at a given temperature, FPs with values less than those of a MOX compound are stable as metals, while those with values less than those of MOX compounds are stable as oxides). Kleykamp H (1985) The chemical state of the fission products in oxide fuels. *Journal of Nuclear Materials* 131: 221–246.

UO₂ pellets

The LWR UO₂ pellet is produced with 95% of theoretical pellet density (TD), and a dish and chamfer are formed on the ends of the pellet, as shown in Fig. 12. These features are incorporated to suppress Pellet-Clad Mechanical Interaction (PCMI) due to thermal expansion and swelling of pellets. In the pellet production process, raw powder is granulated, blended with additive, pressed, and sintered into pellets. Then the outer periphery of the pellet is ground to final pellet dimensions. UO₂ pellet sintering is carried out at about 1973 K in pure gaseous hydrogen and the O/M ratio is adjusted to 2.00. Raw UO₂ powder with excellent flowability and sinterability has been developed and used successfully in UO₂ fabrication. Pellets of higher than 95%TD can be obtained with the use of powders with higher specific surface area.

MOX pellets

MOX pellets for fast reactor fuels are adjusted to the low O/M ratio of 1.98 to prevent oxidation of inner surface of the stainless steel cladding tube, improving fuel and cladding compatibility. The O/M adjustment is accomplished in the sintering process, which is performed in Ar and H₂ gas mixture. Plutonium spots or inclusions in the pellet are an important feature and are limited in the fuel specifications. Plutonium inclusions cause localized hot spots in the fuel pellet and may melt the fuel because a localized higher-than-average fission density is caused by a localized concentration of fissile plutonium atoms. Therefore, the size of the Pu inclusions in the cross section of the pellet as measured by alpha-radiography and Electron Probe Micro Analysis is strictly specified in the fuel specification. The sintering rate of the pellet is also affected by O/M ratio during heating (Nakamichi et al., 2020, Takeuchi et al., 2011). Fig. 13 shows pellet density change with O/M = 2.00 and 1.99 during the sintering process (Nakamichi et al., 2020). The

Fig. 12 Appearance of UO₂ pellets. Image available at https://www.ndc-tokai.co.jp/enterprise/index_fuel.html

Fig. 13 Theoretical density ratio (%TD) of MOX pellets for different temperatures and heating rates. Nakamichi S, Hirooka S, Kato M, Sunaoshi T, Nelson AT, and McClellan KJ (2020) Effect of O/M ratio on sintering behavior of (Pu_{0.3}U_{0.7})O_{2-x}. *Journal of Nuclear Materials* 535: 152188.

sintering rate of stoichiometric MOX is fast and can result in a homogeneous pellet. The activation energy of sintering was evaluated to be 919 and 482 kJ/mol for MOX pellets with O/M = 2.00 and 1.99, respectively. The analysis results from the isothermal sintering test showed that grain boundary diffusion contributes to the sintering of stoichiometric MOX, whereas the sintering mechanism of low O/M pellet was unclear (Takeuchi et al., 2011).

Nitride and carbide pellets

In manufacturing of nitride and carbide pellets (Solntceva et al., 2016; Sengupta et al., 2012), carbo-thermic reduction is generally employed to produce nitride and carbide, as described by the following reactions, respectively.

Uranium and plutonium mixed oxide powders are blended with carbon and heated in N₂ and Ar to obtain nitride and carbide, respectively, and then pressed and sintered into pellets. The materials can be also produced by a hydriding method:

Both materials easily react with oxygen to provide high heat generation. Therefore, the materials must be produced in a glove box filled with Ar gas to prevent ignition by reaction with air.

Introduction

The topic “Design and Fabrication of Fast Reactor Metal Fuels” is quite broad, so the approach used here is to start this article with a short history of the use of metal fuels. Using that as a background, the design and fabrication of a metallic nuclear fuel element is discussed by describing the process used for one particular fuel type, a driver fuel pin (or rod) for a sodium-cooled fast reactor. The 40-year evolution of this fuel type provides a helpful illustration of the technical issues addressed in fuel design as needed to achieve acceptable fuel operation. Although a number of early nuclear reactor designs used metal fuel, including research reactors, the designs described here are for fast reactors.

There is a process to choose the basic fuel type, based on reactor operating conditions (dictates choices for fuel and cladding materials), potential fuel/coolant incompatibilities, required life expectancy (fuel burnup, cladding irradiation exposure, etc.), and other consideration. Knowledge of the reactor operating conditions and any special restrictions as to size or shape influenced by the reactor design will influence the choice of fuel alloy composition and/or fabrication methods. Availability of fabrication facilities and vendors, feed materials, and hardware also influence design choices when dealing with nuclear fuels. Requirements for unique materials or fabrication processes can limit options considerably. These matters, along with experience gained from using a particular fuel design constrain, or even dictate, fuel design characteristics as much as performance requirements.

Design: Fuel alloy and fuel pin design to optimize performance

A subsequent section of this chapter describes the design and fabrication process with a uranium-alloy fast-reactor metallic fuel. Other metals, plutonium and thorium, have also been used in the past as the base metal for the alloy, but most prior experience is with uranium-based alloys. Within that description, the fuel performance features which influence the design and fabrication choices are outlined.

But first, presenting a brief history of metal fuel usage is helpful, followed by fast-reactor fuel designs and use. The final sections of this chapter describe the developments expected to come next—new designs, fabrication technologies, tailored fuel compositions, concern over waste issues, etc.

Metal fuel use, a short history

Originally, unalloyed metallic uranium was used as fuel, but too many applications had problems because of its unpredictable behaviors in lower temperature operation. The alpha phase of uranium is prone to swelling problems, so alloying elements were added to stabilize the gamma phase, which has more-predictable behavior due to its highly symmetric cubic crystal structure. Molybdenum was the most popular alloying element, because it provided the desired gamma-phase stabilization and resulted in suitable solidus and liquidus temperatures that were low enough to facilitate fabrication and high enough to provide in-reactor temperature margin to melting. A variety of reactor types utilized U-Mo metallic alloy fuel in the past. Many of the early pulsed

*Change History: October 2020. Douglas L. Porter and Douglas C. Crawford. Initial issue.

reactors used U-Mo, two with low-alloy alpha-phase U-1.2Mo (alloy compositions are expressed in weight percent), but another five reactors were fueled with an alloy with stabilized gamma-phase (U-10Mo) (Horak et al., 1973). The low alloying of U-1.2Mo was used to produce a small grain size, to reduce the effects of material property anisotropy prevalent in the alpha phase fuels. The higher alloying of U-10Mo eliminated any anisotropic behavior.

Other applications of alloyed fuel included a power reactor, the Organic Moderated Reactor was cooled and moderated by an organic liquid at the Piqua Nuclear Generating Station in Ohio, which was built and operated between 1963 and 1966 as a demonstration by the Atomic Energy Commission (Baumeister and Wilde, 1960). Another, the Hallam Nuclear Power Facility (HNPF), a graphite-moderated sodium-cooled reactor, which operated from 1962 to 1964 in Nebraska, used fuel that consisted of U-10wt% Mo cylindrical rods sodium-bonded to stainless-steel cladding. Fuel development and testing were carried out by Atomics International in the Materials Test Reactor (Willard and Schmitt, 1964).

Some early fast reactors employed U-Mo alloys as the standard driver fuel, and these included the Dounreay Fast Reactor (DFR) in the United Kingdom and the Enrico Fermi Fast Breeder Reactor (EFFBR) in the United States. One of the central reasons to use alloyed uranium in these applications was to control the fuel dimensional changes caused by gas swelling and phase transformations. This was very important for fast reactor applications where fuel temperatures were high (500–800 °C), so the fuel could operate with and be cycled between the low-temperature alpha and high-temperature gamma phases (Cottrell et al., 1964).

The EFFBR was the first commercial fast reactor, located in Monroe, Michigan. A 200-MWt (60-MWe) three-loop design, it was approved by the Atomic Energy Commission in 1955. The fuel was U-10Mo, sodium-bonded to Zircaloy cladding. The geometric design of the fuel assemblies was a 12×12 array of 4-mm diameter fuel elements (or fuel rods). The arrays were held in 67.2-mm square stainless-steel ducts, which are analogous to the square channels used around boiling-water reactor fuel bundles.

The EFFBR fuel prototypes were tested thoroughly before use in Argonne's CP-5 reactor to demonstrate that the U-10Mo alloy could perform to the reactor design specifications. The studies indicated that the primary concern was to ensure that the fuel would maintain the gamma phase during operation. U-10%Mo is now known to accomplish this. The goal of the studies was to provide the best dimensional stability of the fuel.

Alloy choice

The initial, early choice was unalloyed uranium. Uranium exists as several major phases depending on T — α , β , and γ . The low-temperature crystal structures have much less symmetry than the highest temperature form, the gamma (γ) phase. Gamma uranium has a body-centered cubic structure, so most all of its properties, physical and mechanical, are isotropic. The thermal expansion as a function of temperature is the same in all orthogonal dimensions. The alpha and beta phase do not have this symmetry.

It is easier to predict the performance of the cubic phase, so alloying was used to bring the stability of the γ phase at lower operating temperatures. As mentioned earlier, molybdenum was the most common alloying ingredient (Horak et al., 1973; Baumeister and Wilde, 1960; Willard and Schmitt, 1964; Cottrell et al., 1964; Shoudy et al., 1963).

Early studies showed that the fuel growth caused by fission gas generation, or due to thermal cycling, could be very surprising (see Fig. 1) if the fuel pin had an anisotropic crystal structure (from rolling, as shown in the figure) (Chiswick, 1956). In Fig. 1, the material had been rolled to varying degrees of deformation (3–74%) at 300 °C (in the alpha regime), resulting in a crystallographic texture. When thermally cycled in the alpha temperature regime, where the thermal expansion coefficients vary with the crystal orientation, a preferential growth was seen. This was in the absence of irradiation. When irradiated, the growth caused by fission gas bubbles showed similar anisotropy. Because of these phenomena, the isotropic gamma phase was desired, and the early choice of alloying elements were all gamma phase stabilizers, such as Mo.

Note that in Fig. 1, increased deformation (reduction in area) created a crystallographic texture. Smaller grain size enhanced the anisotropic growth. Note also that the decrease in grain size created no such effect if there were no preexisting texture induced by rolling.

After the early transitions of unalloyed uranium to U-10Mo, the emergence of fast reactors influenced alloy design. Mo remained as an option, as shown by the choice of Mo for EFFB. Other options were Zr or Ti, and also a fictitious element, fission (Fs), which was a combination of fission products that were expected to remain after reprocessing. Fs is dominated by Mo and Ru. U-Fs and U-Pu-Fs were studied, and Experimental Breeder Reactor-II (EBR-II) operated for many years using U-5%Fs fuel, including reprocessed fuel (Walters et al., 1984).

In later years, and with the advent of the Integral Fast Reactor program, the reprocessing scheme changed and design changes improved fuel performance, where higher temperature operation and enhanced fuel pin lifetimes were expected. The use of Fs was abandoned. With high-temperature operations, fuels with other characteristics now have more popularity. Uranium-zirconium alloys, specifically U-10wt%Zr, have been used, because Zr increases the melting temperature of the fuel and also seems to provide more protection against fuel-cladding chemical interactions (FCCI). FCCI was expected to be one of the most important factors influencing fuel pin lifetime and therefore influenced fuel alloy design.

FCCI is the mixing, or interdiffusion, of cladding components with the fuel alloy and attendant rare earth fission products (La, Ce, Nd, Sm, and Pr) (Matthews et al., 2017; Keiser, 2012). The zirconium alloys also have an increased melting temperature compared to unalloyed uranium. The things to most avoid in fuel performance are fuel melting and a large number of cladding breaches, and both phenomena are aggravated by FCCI. FCCI creates interdiffusion regions in the fuel and in the cladding, layers of intermetallic compounds. The layers effectively reduce the load-bearing thickness of the cladding by producing weak and brittle

Fig. 1 Photographs from a 1956 study (Chiswick, 1956) of cylinders of uranium thermally cycled 500 cycles from 50 °C to 550 °C after being rolled at 300 °C to a given area of reduction (A) 3–74%, (B) 70%. In (B) the reduction in area was a fixed 70%, but the grain size varied. All samples began at the same 2.5 cm length.

layers at the fuel/cladding interface. Alloying the fuel with zirconium seemed to help mitigate the formation of these layers. Future methods for the mitigation of FCCI are discussed later in this article.

Design and fabrication of sodium-cooled fast reactor (SFR) metal fuels (EBR-II example)

Fuel pin design

As mentioned in the discussion of fuel alloy choice, engineers and scientists responsible for the EBR-II reactor experimented for many years, choosing a fuel alloy that contained a mixture of elements representative of the fission products carried over when using the fuel reprocessing method of the time. The alloy was U-5Fs, where the 5wt%Fs represented alloying contents 2.4%Mo, 1.9%Ru, 0.3%Rh, 0.2%Pd, 0.1%Zr, and 0.01%Nb. Fabrication methods were improved to avoid fuel texturing. The pin design was changed to incorporate a 75% smeared density (calculated by the cross-sectional area of the cylindrical fuel slug divided by the area inscribed by the inner diameter of the cylindrical cladding). The lower smeared density allows the porosity forming in the fuel to connect into a network before the fuel swells to contact the cladding. Fission gas is then easily released, reducing the stresses applied by the swelling fuel. Dimples in the cladding, designed to prevent fuel slug lift-off inside the cladding, were found to shorten the lifetime of fuel pins (they were locations of enhanced stress in the cladding) and were removed. Eventually, lift-off was proved to not be a problem. This history is described in (Walters et al., 1984) and (Crawford et al., 2007). The resultant design, emerging in the final decades of EBR-II operation, is shown in the sketch in Fig. 2. The smeared density concept is shown in Fig. 3.

Fig. 3 shows the cross-section of the fueled area. The smeared density is defined as the cross-sectional area of the fuel slug divided by the area inscribed by the cladding (fuel slug area + bonded-sodium area). In this case, it is drawn to represent 75%, the usual cross-section for EBR-II and Fast Flux Test Facility (FFTF) metal fuel pins.

Fig. 2 A sketch of a sodium-cooled fast-reactor metal fuel pin.

Fig. 3 A cross-section of fuel pin in the fueled area. This design has a 75% smeared density.

Sufficient volume is provided in the plenum space above the fuel column to accommodate the fission gases that are released from the fuel during operation. The fuel is “bonded” to the cladding with sodium (i.e., sodium fills the gap between the fuel slug and the inner cladding surface), to provide for the thermal transfer from the fuel to the cladding until the fuel has swollen to make physical contact with the cladding. The sodium coolant in the reactor flows through a bundle of the pins contained within the hexagonal duct of the assembly. The wire wrap is spiraled around and down each pin. The wire diameter and pitch are designed to maintain spacing between pins and mix the reactor coolant radially as it flows axially from bottom to top of the fuel assembly. The fuel pins were attached to the fuel assembly in a hexagonal grid, allowing close packing but minimizing constraint by the single point of attachment. The slotted lower end plug is slipped onto grid bars (see Fig. 4). This design not only held the pins securely but made the disassembly and reassembly of the fuel bundle possible. Test pins could be examined after a period in the reactor, and the assembly could be rebuilt in new assembly hardware and continue irradiation. The fuel pin design proved to be simple but effective both for fabrication efficiency and experiment functionality. The efficacy of the design was confirmed in larger geometries by a set of irradiation experiments in the FFTF in the United States (Pitner and Baker, 1993).

Fabrication

With the simple design chosen, all that remains is prescribing the best methods to use in the fuel pin fabrication process. Of course, the fabrication method development progressed along with the design evolution. Eventually, a process involving induction melting

Fig. 4 An assembly of fuel pins on the assembly grid bar, allowing for the easy construction of a tightly packed hexagonal bundle of pins. It also allowed the interim examination of test pins (Burkes et al., 2009).

(in a single stage) was chosen, followed by injection casting (Burkes et al., 2009). The injection casting is demonstrated in the sketches shown in Fig. 5. The charge materials are loaded into the crucible and placed in the furnace. The furnace is evacuated, then the charge is melted and stirred both by the induction fields generated by the induction heating coils and also, periodically, manually with a tantalum stirrer. Finally, the quartz molds, coated internally with zirconia powder and sealed at one end, are immersed into the molten uranium alloy, and the furnace is quickly pressurized with argon to quickly push molten alloy into the evacuated molds.

The slugs were demolded and sheared to length. One slug (for EBR-II use, two or three slugs for FFTF metal fuel experiments) was placed in each cladding tube (called a cladding jacket) that was sealed at one end with a bottom end plug and contained an extruded length of sodium. The sodium was briefly melted, and the fuel “settled” to the bottom of the jacket. A top end plug was welded to the upper end, sealing the fuel in the jacket.

The next step was sodium bonding, a process to heat the jacket and its contents at a temperature high enough (550 °C) to wet the outer surface of the fuel and the inner surface of the cladding. While at temperature, the fuel pins were mechanically impacted (dropped a short vertical distance) to settle the sodium further toward the bottom of the fuel rod to force out any gas bubbles trapped between the fuel and cladding. This ensured a good thermal contact between fuel and cladding. Heat generated by the fuel slug was efficiently transferred to the reactor coolant.

While there were some important design and fabrication method improvements made along the way, there were nearly 35,000 pins made from irradiated and reprocessed EBR-II driver fuel; all produced remotely in a hot cell and assembled into fuel pins and assemblies in the 1960s (1964–69). The processes used were very similar to those discussed here (Stevenson, 1987). Of course, there

Fig. 5 The injection casing of metal fuel slugs. (A) A bundle of closed-end molds are suspended over the melt crucible while the charge is melted, (B) the furnace is evacuated and molds are inserted into the melt, (C) the furnace is re-pressurized, filling the molds, and (D) filled molds are held above the melt to cool.

were also many pins fabricated from unirradiated feedstock (167,000 U-5Fs pins as of 1987 at Argonne and 47,000 more at vendors, and another 16,000 pins of U-10Zr at Argonne) until EBR-II was shut down in 1994 (Wilkes et al., 1987; Burkes et al., 2009).

In the future

Designing to mitigate fuel/cladding chemical interaction (FCCI)

FCCI occurs when the fuel (U or Pu) and/or rare earth (RE) fission products (Nd, Ce, Sm, La, and Pr) interdiffuse with cladding constituents (Fe, Cr, and Ni). The intermetallic compounds that result form in layers in the cladding at the fuel/cladding interface. Because FCCI limits the useful lifetime of the metallic SFR fuel, there have been a series of proposed design modifications to mitigate FCCI. One approach inserts a diffusion barrier between fuel and cladding. Zirconium and other materials have been used, either as a liner to the cladding or a coating bonded to the inside diameter of the fuel cladding. Critics of this approach assert that there may be no certain means to ensure the 100% reliability (no breaks in the barrier) of these barriers and that they cannot be considered a mitigation.

Another approach is to use subtle changes in fuel composition to reduce FCCI. There are alloying elements (Sn, Pd, Sb) that form very stable intermetallic phases with the RE fission products (Mariani et al., 2011; Xie et al., 2018), the elements that dominate the FCCI effect in U-Pu-Zr fuels (Keiser, 2012). This effectively reduces the amount of REs available to penetrate the cladding. The formerly used U-5Fs alloy, for which the 5 wt% Fs was a mixture of noble metal fission products (2.4%Mo, 1.9%Ru, 0.3%Rh, 0.2%Pd, 0.1%Zr, and 0.01%Nb), demonstrated some of these effects, showing the FCCI to be dominated by uranium diffusion into the cladding and less RE penetration. REs formed intermetallic compounds with Pd in the U-5Fs (Harp et al., 2020).

The challenge with alloy additions as a means to mitigate FCCI is to perfect the delivery of these elements to allow for the formation of the intermetallic phases through prescribed fabrication techniques and quantities of additives, without allowing an interaction with the alloy, which would minimize their effectiveness and remove Zr from solid solution and thereby reducing the fuel solidus temperature. In addition, it remains to quantify the alloying addition's beneficial effect on FCCI. The use of stronger cladding, such as oxide dispersion strengthened alloys, may also be beneficial, because it is the loss of strength as the cladding thins due to FCCI that allows an early approach to a strain or cumulative damage fraction limit (Briggs et al., 2018). The benefit of stronger cladding material can be easily incorporated into the design limit analyses. Preventing any liquid phase formation with the fuel remains important in this case as well.

That kind of FCCI (melting) also limits fuel operation. That FCCI is eutectic melting, which occurs when the fuel materials, U and Pu, interact/interdiffuse with the cladding, forming low melting compositions. Pu bearing fuels are often limited to a 650 °C peak cladding temperature to prevent this melting behavior. Alloying additions to the fuel and stronger iron-based cladding materials will not prevent this reaction. So perhaps the best, most efficient barrier to FCCI of all kinds is a barrier material inserted between fuel and cladding. Zirconium and vanadium have been effective in preventing the penetration of both fuel and fission products into the cladding (Cole and Keiser, 2007). The challenge for the use of barriers (whether incorporated as tubes, foils, or coatings) is their fabrication with the cladding to ensure a continuous, unbroken barrier layer. So, the co-fabrication of the coatings and liners with the cladding is very important. There have been a number of recent studies to select effective coatings or liners and to find effective fabrication techniques (Ryu and Lee, 2009; Firouzdor et al., 2011, 2013a,b).

Spent fuel storage

One of the other problems with current SFR metallic fuel designs is the disposal of sodium-bonded used fuel. Evaluation by the US Department of Energy determined that neither indefinite storage of sodium-bonded fuel stored at the Idaho National Laboratory nor its direct disposal into a high-level waste repository was recommended because of the chemical reactivity of the sodium and uranium. It is therefore difficult to provide for a way to dispose of the used fuel. Electrochemical treatment to separate sodium from actinide constituents and to produce disposable waste form is the preferred disposition path in the United States for sodium-bonded used fuel. The most recent designs of SFR metal fuels use are 75% smeared-fuel density and are sodium bonded, so pre-disposal treatment is likely to remain a requirement for use of metal fuel.

However, if the sodium bond were not part of the used fuel then it would be less risky to store, and more disposal options could be considered. The problem is that the larger fuel-cladding gap filled with sodium is the design feature adapted for accommodating the swelling of the metal fuel without severely stressing the surrounding cladding. The sodium bond is therefore necessary, at least early in life, to transfer the heat from the fuel slug to the cladding and prevent the fuel slug from overheating and potentially melting.

The obvious alternative to the current design is, therefore, to use another thermally conductive liquid, or gas, something that will not transfer stress to the cladding as the fuel swells. Alternatives to sodium as the thermal bonding agent have been suggested and dismissed because they may cause cladding embrittlement or corrosion (Kamdar, 1983; Lynn et al., 1975). Potential transmutations of the alternative liquid metal, which could cause species to form that may attack the cladding, must also be investigated.

Another possible solution is to fabricate the fuel slug with a tight fit to the cladding and provide fuel space to accommodate fuel swelling elsewhere in the fuel slug. Two suggested alternatives are (1) slotted fuel where the empty space falls on the periphery of the fuel but only at specific areas around the circumference and (2) annular fuel with a fuel centerline void. Fig. 6 illustrates this first concept, using a computer model of fuel swelling to predict how the fuel would swell and contact the cladding.

Fig. 6 A diagram of slotted fuel being modeled to show the temperature distribution and swelling as a function of fuel burnup. (A) Near the beginning of life and (B) after significant swelling. Modeling images courtesy of Dr. Pavel Medvedev, INL.

However, earlier work demonstrated that the fuel can cause the cladding to deform and become unround (Golovchenko, 2011). So further work is needed to test variants of the design for acceptability.

The second concept of a fuel design with no thermal bond material between fuel and cladding is the annular design. Again, the fuel slug must fit tightly within the cladding, but the smeared fuel density is reduced by placing a central void down the centerline of the fuel slug, sized sufficiently to allow for the formation of open porosity (to release fission gas to the fuel pin plenum) by the time the fuel swells to fill in the central void. But the central void is relatively difficult to produce in the fuel by casting techniques, because the small fuel cross-sections challenge mold construction. Fig. 7 shows a sketch of the cross-section of this type of fuel pin, with a 75% design, the same as shown in Fig. 3 for the current, sodium-bonded design.

One barrier to using this design is the difficulty in fabricating fuel slugs in long sections through traditionally used casting methods. Note also that, because the bond-free fuel designs require tight-fitting fuel slugs, the assembly of these designs (placing the fuel in the cladding) is also challenging. The annular fuel could be produced by extrusion or perhaps continuous casting. These alternative fabrication schemes, also suggested to minimize fabrication waste, will therefore be discussed in the next section as one of the new advances in fabrication.

Fabrication solutions

There are a variety of new reactor designs, some using very small fuel components, some very large with long fuel columns. All of these can contribute to new challenges in metal fuel fabrication. So, the development of new designs motivates rethinking the basic fabrication methods to address these new designs and minimize or simplify fuel manufacturing waste disposition.

Even the current methods of fuel fabrication, which may still be utilized in the future, need improvement. The current practice for injection casting leaves a significant heel in the bottom of the crucible, which must be recycled in a future casting. The heel also

Fig. 7 A sketch of annular style fuel with a central void to allow for fuel swelling. This fuel is also represented at 75% smeared density.

picks up impurities, and, after re-melting several times using charges where about half of the feedstock is from the recycled heel, impurities in the fuel charge accumulate to approach impurity limits. At that point, the remaining heel, without costly processing to remove impurities, must be disposed as waste.

There are a number of ways to reduce casting heel waste. One possibility is to redesign the melting and casting process to minimize the casting heel, or even eliminate it with an alternative casting process, such as bottom-pour or perhaps even tilt-pour. A more drastic change would be to cast billets (bottom-pour) and then extrude them into the fuel slugs. Recall that this also eliminates the waste created when quartz molds are broken to retrieve the as-cast fuel slugs.

In fact, extrusion of uranium-based metal fuel for an SFR, EBR-I, was done in the late 1950s (Sawyer, 1958; Kittel, 1959). The Mark-III core was made up of U-2wt%Zr coextruded into Zircaloy-2 cladding. The compound billet (U-2Zr in Zircaloy-2) was extruded. But the mechanical working of the billet into a long cylindrical rod produced a crystallographic texture in the fuel, so the coextruded material was heat treated to remove as much texture as possible after extrusion. The texture can cause anisotropic swelling of the fuel (Sturcken and Walter, 1974).

Recently, extrusion development is underway again, working out a way to produce fuel from cast U-10Zr billets (Pace and Mackowiak, 2018). Similar work is investigating the coextrusion of a UZr alloy in zirconium tubing to produce U-10Zr surrounded by unalloyed zirconium. The goal this time, however, is not to use the coextruded product as fuel and cladding, or, as was studied in the early 1990s (Crawford et al., 1993), to use the co-fabricated product (UPuZr cast into a zirconium mold) as a fuel slug with stainless-steel cladding in a classic solid slug, 75% smeared density design. In that effort, the zirconium tubes were used to eliminate the need for quartz molds, and the resulting Zr layer around the fuel acted as an FCCI retardant. However, the zirconium cracked as the fuel swelled, so areas of fuel and cladding were exposed for interaction. The current efforts intend to extrude a multilayered annular fuel slug that will closely fit into the stainless-steel cladding. This also allows for the removal of bonded sodium and reduces casting slug mold waste. Fig. 8 shows a coextruded U-10Zr/Zr cross-section, and Fig. 9 shows an annular extruded fuel slug. The fuel pieces in the figures have not been heat treated or straightened, and the rough surface is an artifact caused by the use of a worn extrusion die. The best result would be to eventually combine these two design/fabrication features to produce an annular, tight-fitting fuel slug comprised of U-Zr fuel with a thin covering of zirconium. A thinner, uniform zirconium covering than that shown in Fig. 8 would be necessary.

The last waste difficulty that engineers/scientists are addressing is casting mold waste from traditional metal fuel manufacturing. The removal of quartz molds from as-cast slugs leaves the quartz broken into shards with small amounts of adherent fuel. The adherent fuel material complicates the disposal of this waste stream. Studies to find a reusable mold have thus far been unsuccessful (Chen et al., 1992; Shapiro, 1994). In one of these studies, various oxides, carbides, nitrides, and sulfides were used to coat refractory metal molds. Y_2O_3 was the only coating material that effectively prevented the interaction of the molten fuel with the refractory metal mold.

Bottom-pour casting is an idea worth perfecting because it eliminates the heel left in the injection casting crucible after the injection casting molds are filled. Furthermore, a reusable mold might be easier to design for a bottom-pour application.

Fig. 8 A cross-section of coextruded U-10wt%Zr with zirconium. The studies are intended to find a way to simply to add a layer of Zr to inhibit fuel/cladding interactions.

Fig. 9 The end of an extruded rod of annular U-10Zr fuel.

Some very early fuel designs, such as one of the EBR-I fuel designs, used coextrusion of the fuel into the cladding, but these were 100% smeared density and therefore had very low fuel burnup potential. These low-burnup designs are not practical today, but an annular coextruded design shown to be fabricable in usable diameters could be attractive. Particularly so, if the coextrusion process can place a zirconium FCCI barrier between the coextruded fuel and cladding. The tight tolerances on diameter and straightness and the inclusion of a central void are difficult for the small fuel diameters of interest today. In addition, the application of the technology to Pu-bearing or TRU-bearing fuel alloys, is also challenged by the need to operate and maintain the extrusion press within a radiation containment, such as a glovebox.

Conclusions

Experience with the design and fabrication of metallic fuels for sodium-cooled fast reactors now exceeds 60 years. That experience resolved initial barriers to high-burnup fuel use (addressing fuel swelling, fuel/cladding interaction), resulted in designs with relatively large tolerances on dimensions and fuel impurities, and established relatively simple fabrication methods. But the reduced interest in fast reactors in the 1990s removed the impetus to further improve fuel designs and fabrication methods.

But with renewed increased in the applications of fast-reactor technology with reduced waste and increased fuel utilization, significant changes appear possible to:

1. Minimize fuel (and RE fission product) interaction with stainless-steel (austenitic and ferritic/martensitic) claddings. This FCCI has proven to be the effect that limits the operating temperature and burnup of these fuel types.
2. Reduce the waste generated during fuel manufacturing by changing the casting methodology (smaller heels, reusable molds and crucibles, no molds—extrusion, continuous casting).
3. Simplify spent fuel storage, fuel treatment, or reprocessing technologies by removing the sodium bond from the fuel design.
4. Adapt the methods above to fabricate fuel containing plutonium, where the process containment is much more imperative.

Introduction

The modern TRISO particle fuel design is the result of over 60 years of development spanning multiple countries, reactor designs, and research programs (Demkowicz, et al., 2019; Verfonderm et al., 1997). Fundamental features of the fuel design are the encapsulation of fission products in a robust barrier immediately surrounding the fuel and the consolidation of very small encapsulated fuel particles into a matrix that provides a heat transfer path from the fuel particles to the reactor coolant. The intended result is a fuel and fission product barrier that is so reliably robust that reduces reliance on subsequent barriers (fuel cladding, containment building) typical of other reactor and fuel systems.

TRISO fuel design

The concept for a microsphere dispersion fuel with coatings for fission product retention during operation was first developed as a part of the Dragon project in the 1950s (Price, 2012). Evolving from the initial design with a single pyrolytic carbon coating, various additional coating layers were added to the fuel design to improve the consistency with which the particle coatings retained fission products within the fuel (Dayton, et al., 1964; Goeddel, 1964, 1967; Carlsen Jr., et al., 1964; Stansfield, 1991). These innovations culminated in the 1970s with the emergence of the modern TRISO particle, featuring ceramic uranium kernels encapsulated in four distinct coating layers (Verfonderm et al., 1997).

At the center of TRISO particles is a roughly spherical uranium-bearing kernel. The composition and size of these kernels varies with reactor design; however, they are typically composed of either UO_2 , UCO (a heterogeneous mixture of uranium oxide and uranium carbide), or UN with a diameter of 350–800 μm (Stinton, et al., 1982; Phillips, et al., 2012; Lu, et al., 2018). Each of these kernel materials features unique advantages and drawbacks, such as enhanced immobilization of rare earth fission products (UO_2), reduced internal pressure due to reduction of carbon monoxide gas formation (UCO), or increased density of fissile material (UN). As such, kernel composition and size may be tailored for the specific goals of specific reactor designs for which TRISO particle fuel is considered. The kernel itself functions as the first line of containment for solid fission products, in addition to providing the fissile material necessary for the generation of nuclear power, as many fission products are thermochemically stable within the ceramic uranium systems.

While there is significant variation in kernel size and composition between various TRISO particle designs, the thickness and composition of the four coating layers are much more uniform. The nominal layer thicknesses from the reference particle design of the 1970s German AVR program (given in Table 1) have been largely adopted by later designs (Kania, et al., 2013).

The first layer encapsulating the kernel is the buffer layer, which consists of approximately 50% dense pyrocarbon and serves two primary functions. First, the buffer layer provides void space to accommodate fission gases released from the kernel and kernel swelling due to solid fission products. Second, the buffer layer provides distance between the kernel and the other coating layers to prevent concentrated damage in those layers from high-energy fission product recoils. Next is the inner pyrolytic carbon (IPyC) layer. Unlike the buffer layer, the IPyC layer is highly dense so that it functions as an effective barrier to gasses and diffusion

Table 1 Nominal layer thicknesses of German AVR reference TRISO particle design.

Layer	Thickness
Buffer	95 μm
IPyC	40 μm
SiC	35 μm
OPyC	40 μm

of many of the actinides and fission products. The IPyC layer is responsible for contributing to retention of fission gasses during irradiation and protecting the kernel from HCl vapor, which is a byproduct of the silicon carbide (SiC) layer deposition process. The overlaying SiC layer critically serves as both the primary source of structural strength for the particle and the primary barrier to the release of fission products which are not retained within the kernel and IPyC layer. Finally, the outer pyrolytic carbon (OPyC) layer protects the SiC layer from handling damage and serves as a final barrier to fission product release. An image of a TRISO particle with a portion of the coating layers broken away to show the particle's interior is provided in Fig. 1.

The final TRISO particle is roughly spherical, with a design-dependent diameter of 750–1200 μm . These particles are typically compacted along with a matrix material into fuel forms containing thousands of particles. The shape and matrix material depend on the specific reactor design, but most commonly they are spheres or cylinders, as shown in Fig. 2. Various research programs have considered further adaptations of TRISO particles by substituting different layer materials or adding entirely new layers (Verfondern et al., 1997); however, this overview focuses on the standard TRISO design.

TRISO fuel fabrication

Fuel particle fabrication

The first step in TRISO fuel fabrication is to produce the kernels. This is most commonly performed using a sol-gel process with either internal or external gelation (Haas, et al., 1980; Beatty, et al., 1979). In this process, an actinide or actinide mixture is dissolved into nitric acid to form a precursor solution. This solution is generally made with an acid deficiency to allow for increased uranium concentration and to promote optimal gel-sphere properties. As such, in the most common case in which uranium is the sole actinide, this solution is commonly referred to as *acid-deficient uranyl nitrate* (ADUN). Gelation is triggered by the addition of ammonia ions to the ADUN solution either from an external source such as a vapor (external gelation) or from an internal source mixed with the ADUN, in which the reaction is controlled by pH and temperature (internal gelation). In either case, hydrated actinide oxide precipitates are formed into gel (semi-solid) spheres while passing through a heated liquid medium. Gel spheres are then washed with ammonium hydroxide to remove any residual gelation medium or reaction byproducts and to push any incomplete

Fig. 2 3D image from x-ray computed tomography showing TRISO particles distributed within a pebble (left) and a compact (right) (Helmreich, et al., 2018a,b).

reactions to completion. After being washed, gel spheres are dried in either air or steam to remove water, and then they are subjected to thermochemical processing to reach their final desired composition. In the case of UO_2 kernels, this step involves calcining and sintering to convert from UO_3 . For UCO or UN kernels, carbon is dispersed in the initial ADUN solution to provide additional thermochemical reactions with process gasses to convert some or all of the UO_3 to UC, UC_2 , or UN (Stinton, et al., 1982; Hunt, et al., 2014). In all cases, significant shrinkage occurs during conversion from gel spheres to final kernels, so the target gel sphere's diameter must be scaled appropriately to result in a given target kernel diameter.

In general, the kernels fabricated by the sol-gel process using modern methods are round and near the targeted diameter; however, the stochastic nature of the process and the large number of kernels produced in a batch naturally result in some fraction of undesirable kernels. These low-quality kernels are commonly removed from the batch by upgrading based on size and shape (Hunn, et al., 2014). Kernels outside of the desired size range may be removed from a batch by either sieving or by using a roller sorter. If sieving is used, care must be taken not to chip or fragment the kernels by overloading or violently shaking the sieves. Aspherical kernels may be removed by tabling, in which kernels are rolled onto a tilted table in a direction perpendicular to the table's slope. Round kernels roll readily toward the tilt direction in a parabolic arc, while elliptical or faceted kernels will lose momentum and prematurely slide down the table.

After kernel fabrication and upgrading, TRISO coating layers are applied using a fluidized-bed chemical vapor deposition (FB-CVD) system. These systems use an inert gas (commonly argon or hydrogen) to fluidize a bed of kernels, causing them to churn and flow like a liquid, while reactive gasses are introduced to deposit layers onto the kernels. Continuous mixing of the bed promotes even deposition of coating layers by decomposition of reactive gasses. Various properties of the coating layers, such as density, deposition rate, and microstructure, depend upon the fractions of the reactive gasses used and the temperature of the FB-CVD system (Ford, et al., 1973; Hunn, et al., 2008).

The buffer layer is generally deposited using acetylene (C_2H_2), although methane (CH_4) has also been used. Since the buffer layer must be low density to accommodate kernel swelling and fission gasses, buffer deposition is performed at a high rate. Although the IPyC and OPyC layers are composed of pyrolytic carbon (PyC) like the buffer layer, they are required to be near fully dense. As such, differing coating gasses and conditions are used for these layers. A wide range of hydrocarbon gasses have been studied for dense PyC deposition. These gasses include methane, acetylene, propylene (C_3H_6), propane (C_3H_8), and butane (C_4H_{10}); however, modern PyC deposition is commonly performed with a mixture of acetylene and propylene. The primary process parameters controlling PyC properties are the deposition temperature and the partial pressures of reactive gasses (Lowden, et al., 2005). Finally, the SiC layer is deposited using a mixture of methyltrichlorosilane (CH_3SiCl_3) and H_2 , often with the addition of an argon diluent. Key properties of the SiC layer, including density and microstructure, are controlled by the interplay between deposition temperature and the ratio of Ar/H_2 . As with kernels, batches of coated TRISO particles are commonly upgraded for both size and shape using methods such as sieving, roller sorting, and tabling (Hunn, et al., 2014).

Fuel compact fabrication

TRISO particles may be consolidated into a wide range of fuel form geometries within a variety of matrix materials. The most common TRISO fuel forms are cylindrical compacts, which are used in prismatic reactor designs, and spherical pebbles, which are used in pebble-bed reactor designs (Pappano, et al., 2008; Nabielek, et al., 1984; Fütterer, 2021). In both cases, TRISO particles are typically overcoated with a blend of graphite flake and either thermoplastic or thermosetting resin. These overcoated particles (and potentially additional matrix material) are then pressed into the desired shape and heat treated to carbonize the resin, resulting in a compact of TRISO particles in a cylindrical or spherical graphite matrix. Additional features may also be added depending on the specific reactor design are being developed, such as a fuel-free zone on the outer surface or at the center, or an additional coating on the outside of the spherical pebbles to protect the pebbles from handling and collision damage. Alternative TRISO fuel form concepts have been developed, such as SiC matrix compacts (Lu, et al., 2018) and geometrically complex additively manufactured structures (Terrani, et al., 2019; Betzler, 2021).

TRISO fuel characterization and quality control

Statistics of TRISO quality control

Statistical analysis is central to quality control of TRISO particle fuels due to the enormous number of TRISO particles contained within a reactor and the destructive nature of many characterization methods. There are two statistical distributions which are applied to TRISO particle properties: the Gaussian distribution, which is applied to variable properties, and the binomial distribution, which is applied to attribute (pass/fail) properties (Kercher & Hunn, 2005; Hunn, et al., 2009). In both cases, representative random sampling is key to obtaining an accurate indication of quality. For this reason, characterization samples are generally taken from TRISO particle lots using highly randomized methods which sample the full material lot, such as chute or rotary riffing.

Variable particle properties such as kernel diameter are represented by the Gaussian distribution and are characterized by a mean and standard deviation. Determination of these values requires a sufficient number of measurements of the property in question to define a normal distribution. Once this criterion is met, the mean and standard deviation may be used to apply specifications on the mean, as well as the dispersion, with given confidence intervals based on the Student's t-test and tolerance intervals (Hogg & Craig, 1978). For example, the mean kernel diameter could be specified as $350 \pm 10 \mu\text{m}$ with 95% confidence with an additional specification on the dispersion of less than 1% below $300 \mu\text{m}$ and less than 1% above $400 \mu\text{m}$. A randomly representative sample of kernels from each composite batch would then need to be characterized to demonstrate compliance with this specification. Unless otherwise specified, TRISO particle properties described herein are variable.

Attribute particle properties such as defective IPyC are represented by the binomial distribution and are characterized by the number of defects observed in a given sample size. These two values may be used to calculate a maximum defect fraction with a given confidence based on the cumulative value of the binomial distribution (Hirsch, 1957). For example, the fraction of particles with defective IPyC could be specified to be less than $1\text{E-}4$ with a 95% confidence. Given this type of specification, the required sample size to pass may be estimated based on the binomial distribution and an assumed true defect fraction for the material. Due to the long-tailed nature of the binomial distribution and the statistical penalty that accompanies a high degree of confidence, the required sample size is typically much larger than the inverse of the targeted defect fraction. In the previous example of proving a $1\text{E-}4$ (1 in 10,000) defect fraction with 95% confidence, a sample size of nearly 30,000 particles would be required even in the best case of high-quality fuel with no observed defects. In the more likely case that some defects are observed, the required sample size increases even further (e.g., to 119,000 particles if six defects are observed).

Kernel characterization methods

Commonly specified properties for TRISO kernels may be divided into two categories: physical (e.g., kernel size, shape, and density) and compositional (e.g., isotopic and elemental content).

Measurement of physical kernel properties

Kernel diameter and aspect ratio may be measured using shadow imaging, in which a single layer of thousands of kernels is backlit and imaged with an optical microscope. The diameter and aspect ratio of each kernel may then be measured either manually or using automated image analysis software as shown in Fig. 3 (Kercher, et al., 2008). The shadow imaging method relies on the assumption that imaged kernel cross sections are representative of the full three-dimensional kernel geometry, which is reasonable if the kernels are either approximately spherical or are at least randomly oriented. While both kernel diameter and aspect ratio are variable particle properties, aspect ratio is mathematically limited to a minimum value of one. This means that aspect ratio cannot be accurately modeled by the Gaussian distribution, so it must be treated as an attribute property with a critical upper limit.

Density, the other physical property commonly specified for kernels, may be measured by mercury porosimetry (Hunn, et al., 2014). In this method, a kernel sample of known mass is placed in a cell under vacuum and infiltrated with mercury up to a pressure to envelop each kernel without intruding into any surface pores (approximately 25 psi). The volume of the kernel sample is then calculated based on the mass of displaced mercury, allowing for calculation of the average density of the kernel sample based on its

Fig. 3 Segmented shadow image of kernel monolayer (left) and sub-image of individual kernel with automatic measurements of mean diameter, aspect ratio, local curvature, and other geometric parameters (right).

weight. Since this method of density calculation is based on the envelope volume of the kernels (i.e., the volume without intrusion into pores), the resulting density is sometimes referred to as the *envelope density*.

Measurement of compositional kernel properties

Regardless of the type of kernel used in a given TRISO design, an acceptable range of kernel composition is commonly specified as a variable property. This may be given in terms of elemental ratios (e.g., O/U for UO_2 kernels) or in terms of phase ratios (e.g., uranium carbide/uranium oxide for UCO kernels). Elemental ratios for kernels may be determined by a combination of combustion and chemical analyses (Price, et al., 2010). In combustion analysis, kernels are burned, and the mass of elements such as carbon, nitrogen, and oxygen within the kernels are measured based on the resulting combustion gasses. In chemical analysis, kernels are dissolved in nitric acid, which is then analyzed by Davies-Gray titration to assay the total uranium content (Bickel, 1997). Phase ratios for kernels with multiple phases present may be determined by optical microscopy of near-midplane kernel cross sections based on image analysis coupled with the known densities of the phases present (Helmreich, et al., 2018a,b).

The other commonly specified components of kernel composition are the maximum levels for various impurities such as phosphorous, sulfur, and various metallic elements. The allowable quantities of these impurities are typically very low, on the order of hundreds to thousands of parts per million. Impurity levels in kernels are typically measured in the same general fashion as uranium content: kernels are dissolved into a solution which is then used for chemical analysis using methods such as mass spectrometry.

TRISO layer characterization methods

Commonly specified properties for TRISO layers may be divided into variable properties, including the thickness, density, and structure of each layer, and attribute properties, which generally characterize specific defects that may arise during TRISO fabrication.

Variable layer properties

The mean thickness of each of the four TRISO coating layers is generally specified, along with limitations on the dispersion. The thickness of all the coating layers may be measured simultaneously using automated image analysis of optical microscopy images of ceramographic cross sections (e.g., see Fig. 4) near the particle's midplane (Kercher, et al., 2008). This process relies on two key components: the ability to accurately segment layers within the cross-sectional images, and the ability to correct for geometric distortion in the image plane due to distance from the particle's midplane. Several image processing approaches may be applied for accurate layer segmentation. One such method is coupled Bayesian snakes, in which initial estimates of the boundaries for each layer are iteratively updated based on local image intensity, estimated layer thicknesses, and the position of adjacent boundary points until convergence criteria are met (Price, et al., 2007). Correction of the initial measurement of layer thicknesses to account for geometric distortion due to distance from the particle's midplane may be performed by applying a polish-down correction. This correction assumes a near-spherical particle and uses the polish-down distance for the image and the outer diameter of the particle in the imaging plane to estimate the distance to the particle's midplane and project the measured layer thicknesses to the midplane (Helmreich, et al., 2018a,b).

The aspect ratio of TRISO particles may be measured in the same manner as bare kernels, by shadow imaging and image analysis, as previously described. As with kernels, although particle aspect ratio is a variable property, the asymmetric nature of its

Fig. 4 Optical image of a UCO TRISO polished to near midplane (left) and the same image transformed to radius and angle about the kernel's center with layer boundaries marked by automatic segmentation for measurement of mean layer thickness.

distribution precludes the use of Gaussian statistics. As such, the TRISO aspect ratio is treated as an attribute property, with a critical upper limit.

Another TRISO layer property measurable by imaging particle cross sections is the anisotropy of the IPyC and OPyC layers. The anisotropy of PyC represents the degree to which graphite basal planes are either aligned or randomly oriented. Since PyC is optically active, the anisotropy of the IPyC and OPyC layers may be measured by using a polarized light microscope equipped to measure diattenuation: the preferential absorption of light along a specific axis (Jellison & Hunn, 2008). Since an anisotropic microstructure may result in undesired anisotropic behavior under irradiation, specifications on IPyC and OPyC anisotropy are typically one-sided, setting a maximum value only.

Another key variable property commonly measured for TRISO layers is density. This measurement presents a challenge for the buffer layer, as its low strength makes removal from the kernel and other layers infeasible. A solution is to (1) perform an interrupted coating run in which only the buffer layer is deposited, (2) measure the total mass and volume of the buffer-coated kernels by mercury porosimetry, (3) divide the total buffer-coated kernel mass and volume by the number of particles in the sample to convert to averages, (4) subtract out the average mass and volume of the kernels, and (5) divide average buffer mass by average buffer volume to calculate average buffer density (Hunn, et al., 2014). There are several drawbacks to this approach. First, it requires the assumption that the properties of the buffer-coated kernels from the interrupted run will be the same as the full TRISO particles. Second, subtraction of the average mass and volume of the kernels results in a relatively larger uncertainty in the calculated buffer density. Third, this approach only measures the average buffer density without providing any data regarding the statistical distribution.

Density measurement for the other coating layers is more straightforward. Under sufficient pressure, TRISO particles will crack, and the IPyC, SiC, and OPyC layers will separate into fragments. Fragments from each of these layers may then be collected for direct measurement of their density. One highly accurate approach to measuring the density of these layer fragments is the use of a linear-gradient density column (Hunn, et al., 2014). Density columns are constructed by mixing liquids of two different densities and slowly filling a transparent vessel with the mixture while gradually shifting the ratio of the liquids. The result is a column with a density gradient from top to bottom that is dependent on the densities of the liquids used and the mixing ratios (ASTM International, 2018). Layer fragments and calibration floats of known density are added to the column and allowed to settle before their heights within the column are measured. The column calibration is calculated based on the density and heights of the calibration floats, allowing the density of each layer fragment to be determined based on its height within the column.

Attribute layer properties

The stochastic nature of TRISO fabrication processes may result in a low population of various particle anomalies (e.g., coating anomalies caused by over fluidization which ejects particles from the bed during coating layer deposition). Anomalies that may impact fuel performance are regarded as defects, and their allowable populations are specified and quantified to a given level of

confidence based on the reactor design. Characterization of other anomalies that may or may not be directly linked to specified defect fractions can be helpful in providing feedback for process optimization and reduction of the specified defect fractions.

The most critical TRISO defects are failed layers which will allow actinides and fission products to be released from particles during and after irradiation. These defects are commonly identified by performing leach-burn-leach analysis on particles from deconsolidated fuel forms to ensure that any particle failures due to the compacting process are identified (Baldwin, et al., 2014). Particles are first leached in near-boiling nitric acid for a long period (on the order of 24 h). The leachate is then analyzed for uranium content to identify the defect fraction of exposed kernels based on the known uranium content of a single kernel (assuming the uranium kernels of failed TRISO dissolve fully in the solution). The OPyC layer on the particles and any other exposed carbon is then burnt away by air oxidation at high temperature ($\sim 750^\circ\text{C}$). A second leach is then performed in the same manner as the first, but uranium in the second leachate is attributed to particles with a defective SiC layer.

One of the roles of the IPyC layer is to prevent infiltration of HCl gas generated as a byproduct of the SiC deposition process. If unusually high permeability of the IPyC layer allows for HCl infiltration to the kernel, then subsequent exposure to high temperatures will result in dispersion of uranium from the kernel into the buffer layer due to leaching. Identification of defective IPyC in TRISO particles requires them to be heated to trigger uranium dispersion and then examining them by radiography to identify particles with excessive uranium dispersion into the buffer layer (Helmreich, et al., 2017a,b). Counting the number of particles with excessive dispersion out of the total number of particles imaged allows the maximum defect fraction to be determined with a given confidence as described in the “Statistics of TRISO quality control” section. Due to the penetrating nature of radiography and the large number of particles which must be analyzed to determine the defective IPyC fraction, this analysis presents an excellent opportunity for the identification of other particle anomalies as a feedback mechanism to the fabrication process (Helmreich, et al., 2017a,b).

The inclusion of carbon and silicon soot within the SiC layer during coating is known to result in the formation of lenticular flaws which may reduce the strength of the SiC and could result in particle failure (Kinsey, et al., 2010). These defects may be identified by optical analysis of the SiC layer in large numbers of cross-sectioned particles.

Another attribute specification on the SiC layer targets its microstructure. Data indicates that large columnar grains within the SiC layer may reduce fission product retention, as well as layer strength (Petti, et al., 2003). As such, the SiC layer microstructure may be specified to be finer than a given visual standard of undesirable SiC microstructure based on backscattered electron images (BSE) which show grain structure due to the dependence of electron penetration and backscatter on grain orientation. More quantitative methods for SiC microstructure analysis may be implemented based on automated grain size measurement of BSE images (Helmreich, et al., 2020).

Impacts during particle handling may result in cracking and removal of the OPyC layer for some particles. This defect removes the protective layer from around the SiC, which may result in further damage to the particle during handling and compaction into a final fuel form. Due to the significant difference in surface appearance for OPyC and SiC, particles with this defect may be identified by visual inspection of particles with an optical microscope.

TRISO fuel form characterization methods

While TRISO particles are generally similar regardless of specific reactor design, the fuel forms into which TRISO particles are fabricated are diverse, as are their required characterization methods. Specifications on overall shape, the geometry of internal features such as fuel-free zones, the density and geometric distribution of TRISO particles in each unit, and matrix impurity limits are all common. For some reactor designs in which fuel forms are non-static (e.g., pebble bed reactors), additional specifications on fuel form strength and abrasion resistance may be required. However, a detailed description of the various fuel form fabrication and characterization methods which may be applied for differing reactor designs is beyond the scope of this overview.

Summary

Fabrication of TRISO particle fuels is complex, involving gelation of uranium-bearing beads, thermochemical conversion to kernels, deposition of multiple coating layers, and compaction into a final fuel form. Characterization of TRISO particle fuels is even more complex, with multiple variable and attribute properties which must be measured with a high degree of statistical rigor. However, more than 60 years of particle fuel research and development have produced a robust body of knowledge surrounding TRISO fuel fabrication and characterization, enabling the development and deployment of a wide range of reactor designs using this fuel.

Introduction

Research and test reactors serve a vital role in the scientific community and society in general. Contributions include the production of medical isotopes, fundamental scientific studies into the nature of materials, nuclear fuels testing for advanced reactor and commercial applications, and a variety of national security missions. Typically, “research” reactors are defined as small, lower-power reactors under 5 MW thermal (5 MW_{th}), commonly used for education and training, while “test” reactors are larger reactors with missions ranging from isotope production, the accelerated testing of materials and fuels for a variety government and commercial nuclear energy development missions, and the production of intense neutron beams for basic scientific research. Test reactors operate up to several hundred MW_{th}. Due to the expansive range of missions and operational envelopes (e.g., neutron flux, duty cycle, test position size), the fuel systems used for these reactors are also quite varied, including different geometric configurations (plates, pins) and fuel material (oxides, intermetallics, and alloys) as particles dispersed in a thermally conductive matrix or in a solid monolithic fuel form. Fig. 1 provides an illustration of the wide range of operational performance envelopes for several U.S. high-power research reactors (HPRR) that a fuel system must accommodate.

Fuel design considerations

Fuel systems developed for research and test reactors are designed to meet a unique set of requirements and, in many cases, for the highest performance reactors, a high specific power density is required to generate large neutron fluxes in a small spatial volume (on the order of $1 \times 10^{15} \text{ n cm}^{-2} \text{ s}^{-1}$). Compact, large specific power density cores require the fuel to rapidly eject heat, thus the fuel systems for large HPRRs are plate type (with a large surface-to-volume ratio) and are mainly composed of metallic constituents that have a superior thermal conductivity. These reactors operate at much lower temperatures than commercial power reactors, with inlet coolant temperature under 150 °C, therefore the cladding materials can be composed of alloys with a lower melting temperature, such as aluminum.

Because many of the world’s research reactors were originally designed with highly enriched uranium (HEU) fuels (²³⁵U content greater than 90%), there has been a global effort to remove HEU research reactor fuels from civilian commerce, which entails the conversion of existing research and test reactors from HEU fuel to low enriched uranium (LEU) with <20% ²³⁵U content. This effort supports U.S. government and international nuclear nonproliferation goals. As a result, several new fuel systems have been developed, or existing fuel systems altered, to accommodate LEU. This nearly fivefold decrease in enrichment requires an offsetting increase in the fuel uranium density to maintain the overall operational performance metrics (such as power density and fuel dimensions), which reactor owners require for the conversion from HEU to LEU. To maintain the operational performance requirements and the duty cycle of the research reactors, developers of these new fuels must address a variety of challenges, including the development of new fabrication methods and new testing to ensure the changes that have been made to accommodate the higher density fuel do not compromise the fundamental ability of the fuel to meet irradiation performance requirements (Cole, et al., 2021).

Fig. 1 Fuel operational envelopes for several U.S. HPRRs, including the High Flux Isotope Reactor (HFIR), Advanced Test Reactor (ATR), Missouri University Research Reactor, The National Institute of Standards and Technology Reactor and the Massachusetts Institute of Technology Reactor. Power density is directly related to the available neutron flux, while fission density impacts overall fuel and operational cycle management. Adapted from National Academies of Sciences, Engineering, and Medicine (2016) Reducing the Use of Highly Enriched Uranium in Civilian Research Reactors. Washington, DC: The National Academies Press.

The physical form, or geometry, the fuel takes will impact a variety of design considerations and serves several functional objectives. Plate-type fuels are typically made of fuel and cladding layers with high thermal conductivity to aid in rapid heat rejection. The fabricated layers of these composite fuel plates are composed of multiple constituents, with each constituent playing a specific role related to ensuring the fuel can effectively produce high neutron flux, transfer heat, and retain fission products during its entire life-cycle. HPRR plate-type fuel systems are typically based on the dispersion of particles in a matrix or as a monolithic fuel form. **Fig. 2** illustrates the differences between a monolithic fuel and a dispersion type fuel form. Frequently, a barrier interlayer or coating is introduced between the cladding and the fuel to prevent a fuel-cladding chemical interaction. The interlayers are selected to inhibit interdiffusion and have a low chemical reactivity with both the fuel and the cladding.

Dispersion fuels

The original concept of a dispersion fuel was a system with fuel particles surrounded by a matrix that inhibits the transport of fission products and isolates the particles to prevent the interconnection of fission-gas-induced porosity across the fuel bearing region, termed “fuel core,” or “meat” (impacting mechanical integrity and thermal conductivity). The ductile, high-conductivity matrix (typically pure aluminum) also accommodates dimensional changes in the fuel particles that result from the formation of gaseous and solid fission products (e.g., fuel swelling). The cladding provides the main mechanical structure, acts as a barrier to fission product release, and acts as a conduit for the transfer of heat to the coolant. Interlayers (barrier layers or coatings) serve to inhibit the chemical interaction between the constituents’ dissimilar layers that might otherwise compromise the overall fuel system irradiation performance. This design enables the fuel to function up to a very high fission density (i.e., high exposure or high burnup). The intimate contact between the fuel and the cladding and the absence of a fission-gas plenum (as incorporated into light-water reactor and fast reactor fuel systems) means that research reactor fuel must maintain the fission gas in the fuel material itself and accommodate this gas while retaining adequate heat conduction and structural integrity to high burnup levels.

The density of the fuel particles and distribution of those particles within the matrix material will influence the behavior of the fuel during irradiation and its ability to meet reactor performance requirements (because an agglomeration of the fuel particles

Fig. 2 Schematics of a plate-type fuel composed of (A) particle dispersions and (B) of a solid monolithic fuel material. The density of uranium in the monolithic fuel is significantly greater for the same fuel material and the surface area to fuel volume is less. Modified from Rabin B, et al. (2017) Preliminary report on U-Mo monolithic fuel for research reactors. INL/EXT-17-40975 Rev. 3. Idaho Falls, ID: Idaho National Laboratory.

could result in localized hot spots). Historically, as HEU fuels were used, the number of fuel particles per unit volume was markedly lower, but, due to the fuel's high enrichment, reactor power and burnup targets could be achieved. However, converting research reactors to LEU requires an increase in the fuel uranium density (achieved using a combination of high-density compounds and increased fuel particle density) to maintain the same fuel operational performance attributes. Maintaining the same neutron flux, while reducing the enrichment from more than 90% to less than 20% fissionable ^{235}U , requires maintaining the same ^{235}U density by increasing the overall uranium fuel density in the fuel core. In fact, the total amount of uranium needed in the fuel core is even higher than for HEU fuel due to the parasitic neutron absorption from an increased amount of ^{238}U in the fuel.

Monolithic fuel

The monolithic foil fuel form is used to achieve the highest possible density of uranium in the fuel core. This is particularly important for the highest power reactors converting to LEU, which would otherwise require dispersion fuel particle densities beyond those that can be practically fabricated. For the LEU conversion effort, the U-10Mo alloy demonstrates the best combination of uranium density and irradiation performance properties (stable, isotropic swelling behavior due its bcc crystal structure). The surface area per fuel volume in contact with the aluminum matrix and cladding is less for monolithic fuel than for dispersion fuels, which is advantageous in managing fuel-aluminum chemical interactions. The results from the initial irradiation testing of the U-10Mo fuel led to the introduction of a Zr foil interlayer to prevent chemical interaction between the fuel and the cladding. A barrier layer thickness of 25 μm bounds the fission fragment recoil distance, thus preventing fission products from being injected into the cladding.

In summary, after extensive development and testing, an LEU monolithic U-10Mo has been designed for use in U.S. HPRRs, comprised of a foil-shaped U-10Mo fuel core clad in the aluminum alloy 6061 (AA 6061). The U-10Mo fuel alloy is co-rolled with a Zr foil layer on each flat outer surface to obtain a fuel foil. The fuel foil is slit or sheared to size and clad in aluminum using hot isostatic pressing (HIP). This resulted in the foil edges being free of the Zr barrier; however, because the contact surface with the cladding is lower on the edges, the interaction with the cladding is of minimal concern. Alternative methods of applying Zr layers to the fuel foils were explored during development, but these methods did not produce Zr layers with adequate adhesion to the fuel.

Fuel element design

After fabrication, the fuel plates are curved (for reactors using curved fuel plate geometries) and assembled into an element. The plate configurations and elements optimize the neutron flux for a specific core design and application, and curved fuel elements allow the formation of flux traps in the reactor core (irradiation regions of high flux). But the plate curves also improve mechanical stiffness and geometric stability in the high coolant flow conditions needed to adequately cool the plates (ATR maximum flow is $3.09 \text{ m}^3 \text{ s}^{-1}$ (49,000 gal min^{-1}) (Stanley and Marshall, 2008)). Fig. 3 provides a three-dimensional rendering and cross section of a representative element used in the ATR along with an image of the HFIR reactor core composed of an inner and outer fuel element. ATR is designed as a high-power material test reactor requiring large volume test positions and extended irradiation cycles. Because HFIR is designed to generate extremely intense neutron beam lines, the HFIR core is highly compact to optimize the flux in the center flux position of the core. This requires all the HFIR fuel plates to be of the same dimension and uniformly spaced within a cylinder (uniform coolant channels). Geometrically, this can only be achieved with plates formed in an involute geometry

Fig. 3 (A) Three-dimensional rendering and cross section of ATR element and (B) image of HFIR Core (Betzler et al., 2019). The ATR core is composed of 40 fuel elements, each with 19 plates, arranged in a serpentine core with four individual power lobes. The HFIR core is composed of two nested cylindrical elements, inner and outer, containing 369 and 171 involute plates, respectively.

(the shape a string takes when tautly wrapped around another curve). While each plate in an ATR element is exposed to slightly different irradiation conditions, all plates within a HFIR element (inner or outer) encounter nearly identical irradiation conditions.

Fuel compounds and associated properties

The compounds used for research reactor fuel materials include oxides (UO_2 , U_3O_8), intermetallics (U_3Si , U_3Si_2 , UAl_x), and alloys (U-Al, U-Mo). The need for stable fuel behavior up to a high burnup has limited the choice of compounds to only a few, with the selection even further limited to high uranium density compounds when replacing HEU with LEU. **Table 1** lists the most common fuel compounds in use or being proposed for use and their associated uranium densities. As mentioned earlier, a high-density fuel compound or alloy in a monolithic form has the greatest uranium density, permitting a decreased enrichment while maintaining ^{235}U loading. This permits the fuel to achieve the same operational objectives as HEU. U-Mo alloy fuels, while not currently qualified for use in operating reactors, are the subject of a large effort to convert existing HPRRs to low enriched fuel. An additional fuel system composed of a U-Zr-H compound is found in training, research, and isotope-production reactors—General Atomic (TRIGA) reactors—that operates at substantially lower powers and will not be discussed further.

Material properties are needed by fuel designers and reactor operators to evaluate the thermal and mechanical performance of various designs under steady-state and transient operational conditions. In-service performance attributes of interest regarding the fuel system include temperatures, deformations, and stresses—strains that facilitate the identification of limiting operational parameters (e.g., power density) or fuel conditions (e.g., maximum burnup) for use in various reactor applications.

The density and melting temperature of the fuel and cladding are important physical properties that designers must know to determine the limits in operating conditions to prevent the melting or excessive oxidation of the cladding by the coolant (phenomena that could lead to the release of fission products from the fuel). Knowing the thermal conductivity of the fuel core is important to ensuring that the fuel remains below its melting temperature and that temperature dependent processes within the fuel stay within a predictable range. Heat capacity influences the fuel response to rapid power increases during transient or accident conditions. Mechanical properties of the cladding (and dispersion fuel matrix material) impart the ability to mechanically resist or accommodate fuel swelling as fission gases accumulate and exert pressure that can induce plastic deformation or cracking. Understanding the degradation of these properties during irradiation is critical to the evaluation of accident scenarios that could lead to a fuel breach and subsequent fission product release.

Fabrication of plate-type dispersion fuel

Dispersion fuel systems have several unique advantages resulting from the powder metallurgical processes used to fabricate them. The careful selection of fabrication processing parameters can beneficially introduce porosity into the fuel that will accommodate the increased volume of fission gas produced at higher burnup. Burnable poisons can also be introduced into the fuel by mixing them with the powders and can be spatially graded to aid in shaping the neutron flux profiles (allowing the attainment of uniform neutron flux profiles to high fission density). In the absence of a gas plenum, the more open structure of a powder metallurgy produced dispersion fuel accommodates larger quantities of fission gas without a coalescence of gas bubbles that might reduce the temperature threshold for surface blister formation, which is a fuel failure mechanism of concern for aluminum-clad, plate-type fuels (Cole et al., 2021; Beeston et al., 1980).

Powder fabrication

The process used to form the powders used in fabricating dispersion fuels depends on the nature of the fuel compound (Hofman and Snelgrove, 1994; Meyer et al., 2020). For brittle solids, like intermetallic fuel compounds, powders are produced by comminution. This process uses jaw crushers and hammer mills to mechanically break down the brittle cast alloy into a powder, followed

Table 1 Properties of HPRR fuel compounds (Kim, 2012; Meyer et al., 2020; Hofman & Snelgrove, 1994).

Fuel compound	Density (g cm^{-3})	Fuel uranium loading (U g cm^{-3})	Typical enrichment	Typical fuel form (fuel core/fuel system)
U	19.1	19.1	N/A	N/A
U-7Mo	18.4	19.1	LEU	Dispersion/plate
U-10Mo	18.2	16.4	LEU	Monolithic foil/plate
U_3Si	15.6	15.0	LEU	Dispersion rodlet/pin
U_3Si_2	12.2	12.2	LEU	Dispersion/plate
UAl_x^a	N/A	4.5	HEU	Dispersion/plate
U_3O_8	8.4	7.1	HEU	Dispersion/plate

^a UAl_x is a mixture of UAl_2 , UAl_3 , and UAl_4 .

by a sieving of the powders using metal screens to generate the desired distribution of particle sizes. These processes are carried out in inert gas environment to prevent the excessive oxidation of the powders.

Powders from cast alloys of ductile metals are produced through a melt atomization process. In this process, the molten fuel alloy is either poured onto a rotating disk or turned into liquid droplets by rotating an electrode of the fuel material as it is heated. Through centrifugal force and surface tension, small droplets of the fuel material form and rapidly solidify into spherical particles. The fabrication of the metal alloy powders is also carried out in an inert atmosphere because fine metal powders are highly pyrophoric (ignite readily when exposed to oxygen). As with the comminution process, powders can be sieved using metal screens to produce the desired particle size distributions.

Oxide powders, such as U_3O_8 , are produced through inorganic precipitation processes. This is followed by a multiple stage calcining processes at an elevated temperature to produce the desired high-density powders. Following these steps, the fuel material is ground to produce the final powder size distribution.

The images shown in Fig. 4 are of as-fabricated dispersion fuels illustrating the differences in particle geometry between powder fabrication methods. Tailoring the particle size distributions enables an increased packing density of the particles; however, there is a practical limit of $\sim 50\%$, by volume of fuel particles, where fabrication becomes impractical.

Roll bonding of fuel plates

Powder components of the fuel core (fuel powders, Al matrix powders, and, if needed, burnable poisons) are placed into a die and compacted to form the consolidated fuel core. Fabrication of dispersion-based research and test reactor fuel plates uses a picture frame technique to produce the fuel. This technique was used for a variety of fuels, including $U-Al_x-Al$, U_3Si_2-Al , and U_3O_8-Al , and has been in practice for more than 50 years to produce research reactor fuel. The fuel core compact is assembled inside of a rectangular opening machined into a sheet of Al alloy fuel cladding, resembling an open picture frame. The top and bottom plates of the fuel-cladding material are assembled with the fuel-containing layer to form the complete assembly (Fig. 5 provides a schematic of the fuel plate constituents). The entire assembly is then hot rolled and cold rolled to bond the layers together.

One of the significant challenges in producing fuel plates with a high volume fraction of fuel particles is a phenomenon termed “dogboning” (Beeston et al., 1980). Regions of the fuel compact thicken during rolling (typically the leading and trailing edge of the

Fig. 4 Scanning electron microscope images of (A) atomized particles of U-7Mo and (B) comminuted particles of U_3Si_2 fuel. Adapted from Keiser DD, Jr., et al. (2020) The use of U_3Si_2/Al dispersion fuel for high power research reactors. *Journal of Nuclear Materials* 528: 151820.

Fig. 5 Schematic of the picture frame method of roll bonding research reactor fuel. The dark rectangle represents the powder compact of fuel particles dispersed in a matrix with or without burnable poisons.

compact), which can lead to a thinning of the cladding to unacceptable levels over these thickened fuel core regions. To remedy this issue, nonrectangular compacts with tapered ends enable the production of fuel plates with more uniform fuel cores and adequate cladding thicknesses.

Following rolling, the plates are blister annealed (i.e., heated and held at an elevated temperature to ensure the assembly does not delaminate due to the expansion of entrapped gas). Blister annealing is followed by rough shearing, by an ultrasonic inspection for debonded interfaces and to measure the minimum cladding thickness, by final sizing, and by radiographic inspection for uranium homogeneity.

After fuel plate fabrication, the plates are mechanically formed into the final geometry (typically curved) and assembled into the elements. Many of the elements for the high-power reactors using plate-type fuels are fabricated by mechanically swaging the plates into side rails, although some elements (notably HFIR) are assembled by welding the plates into the element side rails.

Fabrication of plate-type monolithic fuel

The high-density LEU U-10Mo monolithic fuel system has been developed to enable the conversion of HPRRs. The general fabrication process of the U-Mo monolithic fuel system is (1) alloying and casting, (2) foil rolling, (3) bonding of the cladding using a HIP, and (4) finishing and inspection for quality assurance. The following descriptions provide examples of the overall generic process developed at the lab-scale for fabricating LEU monolithic fuel in the U.S. The adaptation of the lab-scale process to the commercial scale has led to some variation in specific details, some of which are proprietary to a particular commercial fuel vendor. However, the basic four-step process described above is the same. Fig. 6 provides a flow diagram with more details of the processes within each step.

Casting and alloying

Alloying is performed through the vacuum induction melting of U and Mo metals at a temperature between 1400 °C and 1500 °C. Because the melting point of Mo is 2623 °C and that of U is 1132 °C, Mo dissolution and alloying into molten U takes place. To expedite alloying, a Mo powder, foil, or sheet is often used to increase the contact surface area. To obtain an LEU alloy having a 19.75% ²³⁵U enrichment, HEU, depleted uranium, and natural uranium metal source material is utilized in the alloying process. Alloying is performed using graphite crucibles and molds with a protective coating (e.g., erbium oxide) that prevents the interaction of the molten alloy with the graphite crucible. To establish the desired alloy compositions and homogeneity, alloy melts may be broken up, sampled, and remelted several times, and compositional adjustments made as needed by foundry personnel. The composition of the fuel alloy utilized for monolithic fuel plates is designated as U-10Mo, with ± 1 wt% Mo content being acceptable. In preparation for U-10Mo fuel foil fabrication, rectangular ingots are cast. Once cooled, cast ingots are machined to remove surface imperfections and any alloy-mold interaction products to produce the starting coupons used for foil fabrication. Cast coupons are radiographed to ensure inclusions or voids that can lead to unacceptable foil rolling are not present.

Fig. 6 Flow diagram illustrating the processes used to fabricate U-10Mo monolithic fuel plates. Adapted from Rabin B, et al. (2017) Preliminary report on U-Mo monolithic fuel for research reactors. INL/EXT-17-40975 Rev. 3. Idaho Falls, ID: Idaho National Laboratory.

Foil fabrication

The coupons are homogenized at 900 °C for 144 h under a vacuum to prevent the oxidation of the reactive uranium. Following homogenization, two Zr foils are placed on the outside flat surfaces of the coupons to form a stack and the stack is hermetically sealed in a carbon steel can to prevent oxidation. The ingots are individually hot rolled after preheating the can to 650 °C. Cans are passed through a rolling mill several times to incrementally reduce the foil thickness. The number of rolling passes varies based on the target thickness reduction planned for cold rolling. As needed, the cans are placed back into the box furnace and reheated to maintain the hot rolling temperature. After hot rolling to ensure the Zr layer is bonded, the foils are removed from the cans and cold rolled directly. This is to bring the final thickness of each cold rolled foil to the desired final thickness. Finished cold rolled foils are examined for edge cracking. If edge cracking is observed, cracks are removed via shearing to prevent cracks advancing during storage.

Plate fabrication—HIP bonding of Al cladding

The HIP process for bonding involves the application of pressure and temperature to produce a solid-state joint formed through a combination of mechanical deformation and interdiffusion at the bond line. The joining and forming of metals by HIP is a common fabrication process used for a variety of industrial applications. One of the main difficulties in bonding aluminum alloys is the native oxide that forms on the surface. Joining processes that break up the oxide tend to improve bonding and includes an application of pressure or roughening of the surface. A fairly extensive amount of literature exists on roll bonding to produce composited sheets of aluminum to improve strength, while HIP technology as applied to joining of aluminum sheet is less mature.

During the fabrication development of the U-10Mo fuel, extensive effort went into ensuring adequate and reproducible bonding between the fuel foil and the Al alloy cladding. It is essential to maintain intimate contact between the interlayers to make sure heat transfer from the fuel to the cladding is not perturbed. The HIP bonding process was developed precisely to accomplish this. The temperature of the HIP process produces an interaction layer (evidence of metallurgical bonding) while limiting its extent so as to not negatively impact overall fuel performance. Adequate cladding-cladding bond strength is established through fabrication process controls and a demonstration that the bonding of the Al alloy cladding is adequate through extensive irradiation testing.

In the HIP fabrication process originally developed at Idaho National Laboratory (Jue et al., 2010; Rabin et al., 2017), the surfaces of two sheets of Al cladding are mechanically roughened. A rectangular recess is then machined into to one sheet, which is thicker than the other, to position and hold the U-10Mo foil. The sheets are then chemically cleaned and rinsed in preparation for bonding. HIP bonding entails the fabrication of a stainless steel “can” to hold the fuel plate assemblies. A steel plate, referred to as a “strong back,” and Grafoil sheets separate each assembly. The HIP can and fuel assemblies are then baked at an elevated temperature to remove entrapped gas prior to being seal-welded. The optimum time and temperature for HIP processing was determined to be 90 min at 560 °C, which minimizes the extent of the interaction between the fuel and the Zr diffusion barrier. The finished plates are then sheared to size. The excess material sheared from a plate typically undergoes a bend test, bending the material back and forth over a radius, to further ensure the Al cladding is adequately bonded. For final inspections, the fuel plates undergo ultrasonic testing to ensure the adequate bonding of the cladding interfaces, radiography to ensure the fuel location and uranium loading meet specification, and dimensional and visual inspection.

A subset of cladding material trimmed during sizing operations or from archival unirradiated fuel plates may also undergo scanning electron microscopy (SEM) to ensure a good metallurgical bond has been produced. A typical cladding-cladding bond-line analysis on fresh fuel is illustrated in Fig. 7. The intent of the analysis is to examine the bond line, ensuring there are no gross defects

Fig. 7 Secondary electron image taken by SEM along with elemental EDS maps illustrating the cladding-cladding bond line and observed formation of magnesium- and silicon-rich particles at the interface, along with an elevated oxygen concentration.

or cracks, and to perform chemical analysis, such as energy dispersive x-ray spectroscopy (EDS) mapping, inspecting the character of the precipitates in the matrix and along the bond line. As these precipitates tend to be brittle intermetallics, their density must be known and controlled to ensure the strength of the bond line is not compromised. Because HIP bonding involves less plastic deformation than the roll-bonding process described for powder metallurgy dispersion fuels, the extent of grain growth across the bond line (resulting from alloy recrystallization during hot processing) is substantially lower. Roll bonding produces growth of 20–80% of the grains across the interface (a metric used to verify adequate bonding), while the HIP bonding typically produces growth of no more than 10% of the grains across the interface, thus making this measurement unreliable in assessing cladding-cladding bond integrity. Efforts to develop fabrication inspection criteria and process controls to ensure adequate bond integrity across all constituent interfaces is an important aspect of commercializing the overall fuel fabrication process.

Glossary

Critical mass The fissile or fissionable material mass at which criticality is achieved for a given configuration.

Criticality accident The release of energy as a result of accidentally producing a self-sustaining fission chain reaction (Paxton, 1989). A criticality accident occurs essentially instantaneously and is a hazard mainly to workers within about 4.6 m (15 ft) of the accident.

Criticality safety index A dimensionless number assigned to and placed on the label of a fissile material package to designate the degree of control of the accumulation of packages during transportation. This is derived as the number 50 divided by a number of packages, N, that can be shown to be subcritical for packages subjected to normal conditions of transport or hypothetical accident conditions.

Fissile nucleus A nucleus capable of fission by thermal neutrons, provided the effective neutron production cross section, $\nu\sigma_f$, exceeds the effective absorption cross section, σ_a (Paxton, 1989). The fissile nuclides of interest in Nuclear Criticality Safety are ²³³U, ²³⁵U, and ²³⁹Pu.

Fissionable nucleus nuclides capable of sustaining a neutron chain reaction with neutrons of some energy (Paxton, 1989).
hydrogen-to-²³⁵U ratio or hydrogen-to-U ratio (H/²³⁵U or H/U) The atomic ratio of hydrogen to ²³⁵U or to uranium, respectively, in a solution or hydrogenous mixture.

K-effective (k_{eff}) For a chain-reacting system, the mean number of fission neutrons produced by a neutron emitted in a previous fission during its life within the system. It follows that that $k_{eff} = 1$, if the system is critical, $k_{eff} < 1$, if the system is subcritical; $k_{eff} > 1$, if the system is supercritical (Paxton, 1989).

Nuclear criticality safety protection from the consequences of a criticality accident, preferably by prevention of the accident (Paxton, 1989).

Introduction

Nuclear Criticality Safety (NCS) is a field of nuclear engineering dedicated to precluding criticality accidents during operations with fissionable materials outside of a reactor. For NCS the fissionable nuclides of practical interest are ²³³U, ²³⁵U, and ²³⁹Pu. For establishing a fission chain reaction, the fissionable material should contain a sufficient fraction of fissile isotopes. Fissile materials have

been available in significant quantities since the Manhattan Project in World War II as a result of uranium enrichment and plutonium production operations to support defense programs. Since then, large quantities of fissionable materials have been processed, handled, transported and stored. During hands-on operations with fissionable materials, NCS is necessary to ensure a criticality accident does not occur. Since 1943, there have been 22 process accidents that have resulted in 9 deaths, 33 over-exposures to radiation, and 2 significant over-exposures resulting in physical worker harm, e.g., limb amputations. (McLaughlin, et al., 2000) Criticality accidents have occurred in the United States (7), former Soviet Union (13), United Kingdom (1), and Japan (1) (McLaughlin, et al., 2000). Process criticality accidents are less frequent and tend to be less severe than other industrial hazards, e.g., mechanical and electrical accidents, trips, falls, etc. According to the United States Department of Labor, there were 4779 worker fatalities in process accidents compared to zero process criticality accidents in 2018 (Anon, 2019).

The purpose of this article is to discuss the applicability of NCS to the Light Water Reactor (LWR) Nuclear Fuel Cycle (Fuel Cycle). The LWR fuel cycle in the U.S. currently does not include spent fuel reprocessing or a high-level waste repository for long-term disposal of spent fuel. NCS concerns for these activities are similar to other processing and storage activities. Further, NCS for fissionable material operations in nuclear defense activities are not discussed.

NCS fundamentals and background

As previously discussed, the nuclear fuel cycle involves performing hands-on operations with fissile materials, mainly ^{233}U , ^{235}U , and ^{239}Pu , during handling, processing, storage, and transportation. Based on the aforementioned process criticality accident history (McLaughlin, et al., 2000), there are definite hazards for workers performing these activities. The criticality hazards for the nuclear fuel cycle vary as a result of the characteristics of the facilities and locations where these materials are processed, handled, stored or transported. For these situations, the following characteristics are important to consider for precluding a criticality accident:

- Fissile material nuclide (^{233}U , ^{235}U , or ^{239}Pu) mass present (mass),
- Neutron absorption by non-fissionable nuclides present with fissionable materials (absorption),
- The shape of fissionable material, i.e., spherical, cylindrical, etc. (geometry),
- Neutron interaction with other adjacent masses of fissionable material (interaction),
- The concentration of fissile nuclides in a solution or solid material (concentration),
- Presence of moderating compounds, e.g., water, oil, plastic, with the fissile nuclides, which can significantly reduce the critical mass needed for a criticality accident (moderation),
- The enrichment of the fissile nuclide or quantity of the fissile nuclide in uranium (^{235}U) or plutonium (^{239}Pu) (enrichment),
- Available neutron reflecting materials, e.g., water, concrete, steel structures, worker bodies, etc., outside the fissile materials that are capable of scattering back to the materials neutrons that would have otherwise escaped (reflection) (Paxton, 1989), and
- Volume of the fissionable material system (volume).

As an example, the critical mass of enriched uranium varies significantly depending on these characteristics and what the form of the fissile/fissionable material is in: solution or slurry, powder, or solid metal. To help manage the risk of criticality accidents in nuclear facilities throughout the nuclear fuel cycle, consensus standards have been developed domestically (American National Standards Institute, 2020) and internationally (International Standards Organization (ISO), 2020) for nuclear facilities to implement to assist with the generation of NCS controls and limits.

NCS computational tools and validation of computational methods

Producing NCS controls and limits requires NCS staff to work with process operations staff to determine the normal and credible abnormal conditions for the process. Normal conditions are those operations performed in accordance with an operating procedure. Obviously, the fissile process shall be designed such that these operations remain safe or subcritical ($k_{\text{eff}} \leq 1.0$) at all times during normal operations. Occasionally, equipment failures or personnel errors occur during process operations. Those failures or errors that are credible are considered in NCS analysis and are used to derive appropriate controls on NCS parameters, e.g., mass, moderation, etc., and control limits to ensure the consequences of a credible abnormal condition is subcritical. The consequences of a credible abnormal condition rely on the formality of operations, safety culture health, and process characteristics to determine the magnitude of the credible abnormal condition, which might consist of full water flooding rather than partial flooding of a fissile process or an over-accumulation of fissile material of a credible magnitude, such as accumulating 5000 g of plutonium for a process with a mass limit of 4500 g of plutonium.

NCS engineers perform NCS analysis using a computer code system, such as SCALE (Rearden, 2016), using the most recent neutron cross sections to calculate the k_{eff} of the normal or credible abnormal process configuration. A consensus standard is available (American National Standards Institute, 2008) to provide guidance to those performing k_{eff} calculations to ensure normal and credible abnormal conditions are subcritical. Validation is the process of quantifying the suitability of a computer code system for use in NCS analysis by comparing calculation results with the results of critical benchmarks ($k_{\text{eff}} = 1.0$) to establish the appropriate bias and bias uncertainty (American National Standards Institute, 2008). Further, uncertainties in the data, such as benchmark

descriptions, calculational models for the benchmarks, and the calculational methods (code bugs, nuclear data errors, etc.), need to be considered in the validation to ensure the upper subcritical limit is not exceeded during process operations.

It should be noted that the k_{eff} is not a measure of safety margin of a fissile process but, instead, represents the neutron balance of the process (neutron production and losses). The upper subcritical limit (USL) limit on a calculated k_{eff} value is established to ensure that calculated values represent a subcritical system. Consensus standards recommend the USL be less than unity ($k_{eff} < 1.0$). The USL is typically lower for fissile material configurations with few or no critical experiment benchmarks and higher when there is more experimental benchmark data to use for validation purposes, to provide additional safety margin to compensate for uncertainty of lesser-known behavior. To ensure conservatism, some regulators will mandate lower k_{eff} USLs, e.g., $k_{eff} \leq 0.95$, without a technical basis. NCS engineers will tend to apply administrative margin to reduce the USL further when experimental benchmark data is sparse, nuclear data is uncertain, or operational parameters are not well constrained to ensure NCS for certain fissile processes, such as with solution operations for which concentrations or other operational factors are not well known.

Criticality accident concerns in the light water reactor fuel cycle

The Light Water Reactor (LWR) fuel cycle involves the processing, handling and storage of fissionable materials. The LWR fuel cycle is summarized in this section with an emphasis on those fuel cycle steps where accidental criticality is credible. Although accidental criticality has significant worker safety concerns for some fuel cycle steps, NCS concerns must be balanced with other worker safety concerns, overall worker risk, and cost versus benefit. NCS practice includes reviewing fuel cycle processes and implementing effective engineered and administrative controls in accordance with facility procedures and the NCS consensus standards. Fig. 1 illustrates the LWR fuel cycle with the blue boxes indicating those activities that do not require NCS controls (because criticality accident is not credible) and the black boxes indicate activities that require NCS controls (criticality accident is credible) (Knief, 1985). The credibility of a criticality accident depends upon health of the formality of operations and safety culture, location of the facility, age of the facility, worker experience, and other factors. The dashed lines connecting the boxes indicate the front end of the fuel cycle and the solid lines show the back end of the fuel cycle. Reactor operations are not considered to be within the purview of NCS consensus standards, because other nuclear safety controls are in place to ensure criticality in reactors is controlled. The NCS concerns in each LWR fuel cycle step will be discussed in subsequent sections. Safety considerations in the design, licensing, operation and decommissioning of nuclear reactors are addressed by Rempe (2021).

Uranium mining, milling, and processing operations

Uranium ore extracted from mining activities has an enrichment of about 0.711 weight (wt.) percent (%) ^{235}U and 99.3 wt. % ^{238}U ; this is natural enrichment. Ores are milled and then leached with chemicals to produce yellow cake (U_3O_8). Mill tailings leached of uranium (but consisting of more than 99% of the ore mass) are disposed. The yellow cake is then processed at conversion plants to chemically react the U_3O_8 with fluorine to generate uranium hexafluoride (UF_6) gas that is then solidified for transportation to uranium enrichment facilities (Freiwald, LASL-75-15, 1978). Due to the low concentration of ^{235}U in the uranium (i.e., at natural enrichment), there are no credible NCS concerns for these materials in nominal fuel cycle processing. Natural uranium can be made critical only under conditions involving heterogeneous arrangements (appropriate diameter and spacing) of uranium metal rods in water. The minimum possible enrichment of uranium in a homogeneous mixture with water under optimum conditions of neutron moderation and neutron reflection is about 1 wt. % ^{235}U (Thomas, 1978). Mining, milling, and processing operations are limited to natural enrichment, 0.711 wt. % ^{235}U , and will remain subcritical during these activities under any foreseen conditions.

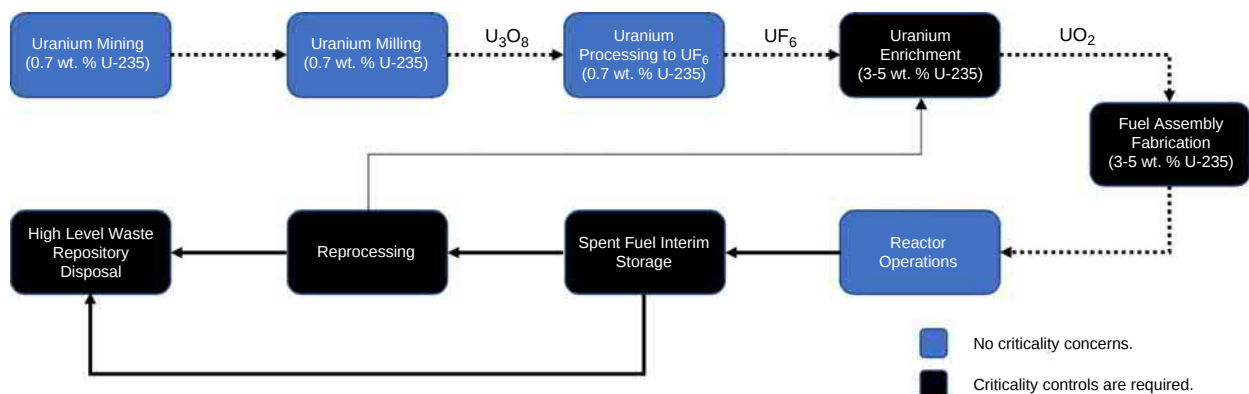

Fig. 1 Light water reactor fuel cycle.

Uranium enrichment operations (3–5 wt. % ^{235}U)

Enriched uranium is needed to fuel LWRs for electrical power generation. Uranium is enriched by increasing the content of ^{235}U in the natural uranium from 0.711 wt. % ^{235}U to about 3–5 wt. % ^{235}U . In the U.S., most uranium was enriched at the Oak Ridge Gaseous Diffusion Plant in Oak Ridge, TN, the Portsmouth Gaseous Diffusion Plant in Piketon, OH, and the Paducah Gaseous Diffusion Plant in Paducah, KY. These enrichment facilities were closed down in 1985, 2001, and 2013, respectively. In 2004, a Gas Centrifuge enrichment facility began production in Eunice, NM, to continue enrichment operations in the United States for LWR operations.

Gaseous diffusion enrichment process

The Gaseous Diffusion Process involves forcing uranium hexafluoride gas, UF_6 , through a converter containing a diffusion membrane that slightly increases the enrichment the lighter ^{235}U isotope. This process requires large compressors that maintain a high pressure on the feed side of the diffusion membranes to ensure sufficient flow rates to make an efficient process (Reed, 2011). Enriching ^{235}U to 3–5 wt. % for the LWR fuel cycle requires the process to be repeated many times due to the low enrichment efficiency of each diffusion stage. The Gaseous Diffusion cascade is safe from an NCS perspective by controlling moderator (humid air) inside the cascade piping. The water in humid air can react with UF_6 gas to form hydrated uranyl oxyfluoride compounds ($\text{UO}_x\text{F}_y \cdot z\text{H}_2\text{O}$) that can settle and deposit locally. These deposits, commonly UO_2F_2 , can grow over time in the vicinity of a breach in the gaseous diffusion cascade that can result in a condition (critical mass of ^{235}U that is moderated) that can support a criticality accident. The approximate minimum critical mass of ^{235}U is 7.6 kg for 3.0 wt. % ^{235}U enrichment and 3.0 kg for 5.0 wt. % ^{235}U enrichment at a hydrogen-to- ^{235}U (H/ ^{235}U) ratio, or moderation level, of about 500 (Jordan and Turner, 1992). In the 1990s, two significant uranium deposits (479 kg U and 98.5 kg U with enrichments of about 3.34 wt. % ^{235}U) were found in cascade process gas piping at the K-25 Gaseous Diffusion Plant in Oak Ridge, TN, resulting from the accumulation of uranium from a humid air in-leakage over a long period of time. Although a criticality accident was not possible due to the mass, deposit geometry, and level of moderation (H/U of 3.5), the unanticipated and undetected accumulation of enriched uranium underscores the importance of NCS principles to fissionable material processing. Gaseous Diffusion plant operations require large, powerful, pumps and support equipment that are unfavorable from an NCS perspective.

Gas centrifuge enrichment process

The Gas Centrifuge Enrichment process is currently the enrichment method in the United States. Unlike the Gaseous Diffusion Process, the Gas Centrifuge Enrichment Plant has been designed to be safer from an NCS perspective. The plant design assumes a maximum plant enrichment of 6 wt. % ^{235}U , although the maximum planned enrichment will not exceed 5 wt. % ^{235}U under normal and credible abnormal conditions. In addition to controlling the uranium enrichment, process equipment dimensions are also credited for safety based upon the geometrical dependencies identified in NCS criticality safety analysis. For example, the gas centrifuges and process gas piping containing gaseous UF_6 are designed to be less than the critical diameter (at which $k_{\text{eff}} = 1$) of an infinite cylinder with full water reflection, which is 24.4 cm (9.6 in.) (Louisiana Energy Services, 2005). A safety factor of 0.9 is applied to this critical diameter to derive a safe diameter: the maximum diameter of gas centrifuges, chemical traps, process cold traps, and process gas piping, then, is 21.9 cm (8.6 in.). Vacuum cleaners, oil containers, and UF_6 pumps are designed based on a safe volume for 6 wt. % enriched uranium: 18.0 L (4.8 gal) (Louisiana Energy Services, 2005). UF_6 feed cylinders (identified as 48X and 48Y cylinders) and UF_6 product cylinders are safe from an NCS perspective with a limitation on available moderator inside the cylinder with solid UF_6 present. Passive engineered features considered early in the plant design makes NCS less reliant on administrative controls and human interaction over the life of the plant/facility. It is not possible to totally engineer out the possibility of human error, but NCS is significantly enhanced with passive and active engineered controls. Active engineered controls, such as control valves, require more human interaction over time for operation and maintenance and allow more opportunity for error, while passive engineered controls, such as equipment dimensions, provide more robust protection against human error. Administrative controls, such as limits to fissile mass or fissile concentration allowed in a process, are also used for NCS when engineered controls cannot be used.

Laser-based uranium enrichment

A proposal for a uranium enrichment considers a laser-based enrichment technology to enrich natural (0.711 wt. % ^{235}U) UF_6 gas. Natural UF_6 gas is separated into a product UF_6 gas stream that can be enriched up to 8 wt. % ^{235}U and a tails stream that is depleted in ^{235}U (United States Nuclear Regulatory Commission, 2012). The cascade or gas handling area of the facility will utilize lasers sufficiently tuned to excite the gaseous UF_6 molecules to separate ^{235}U from ^{238}U in the UF_6 feed stream. The tails stream that is depleted in ^{235}U , is treated in a similar way as depleted UF_6 in gaseous diffusion or centrifuge enrichment processes. NCS is ensured through limiting uranium enrichment, limiting moderation and controlling the size of the equipment (geometry).

Fuel assembly fabrication

High-purity, solid UF_6 is shipped from the enrichment facilities to fuel fabrication facilities, typically in 30B containers. The 30B containers can be used to ship UF_6 up to an enrichment of about 5 wt. % ^{235}U , with NCS limits on volume, interaction (spacing

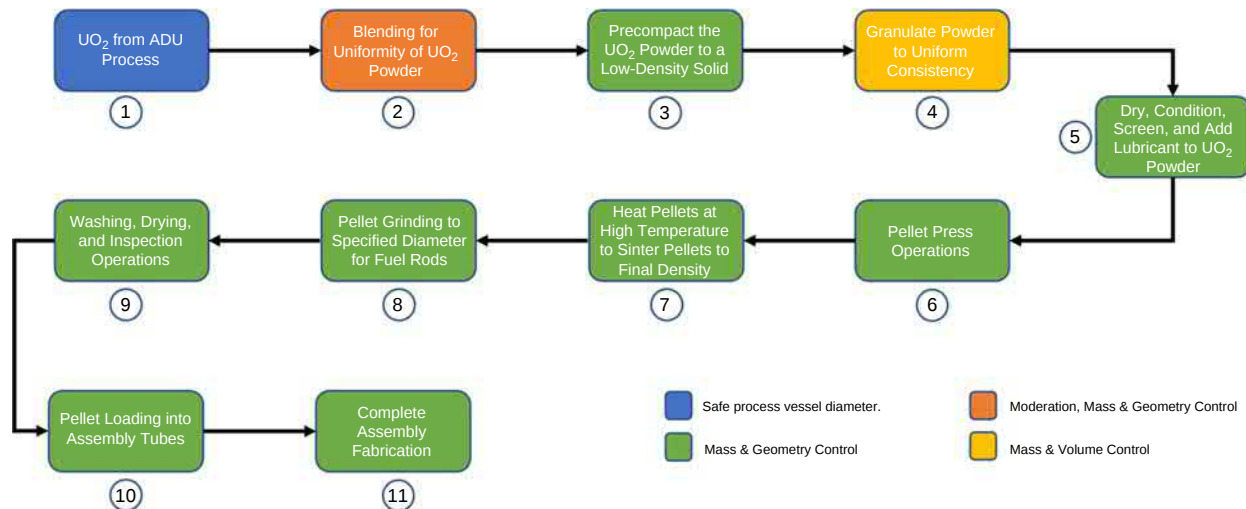

Fig. 2 LWR fuel fabrication process and NCS controls needed for subcriticality. Adapted from Knief RA (1992) *Nuclear Engineering—Theory and Technology of Commercial Nuclear Power*. Washington, DC: Hemisphere Publishing Corporation.

between containers), and moderation (Knief, 1985). Fig. 2 illustrates the LWR fuel fabrication process and identifies the NCS controls required to maintain subcriticality during normal and credible abnormal conditions.

UF₆ to UO₂ conversion processes

The conversion of solid UF₆ feed to UO₂ powder is more challenging from an NCS perspective because the uranium is present as aqueous solution. The critical mass of uranium under optimum water moderation and reflection conditions is significantly reduced from tens of kilograms for solid materials (metal, oxides, and oxide powders) to a kilogram or less when the uranium and moderator (water, acid, etc.) are intimately mixed. There are two main UF₆-to-UO₂ conversion methods utilized in the United States: 1. The Ammonium DiUranate (ADU) process and the 2. Ammonium Uranyl Carbonate (AUC) process. The ADU process involves the hydrolysis of UF₆ with water to form UO₂F₂ and hydrofluoric acid in an aqueous solution (DeLuca and Maas, 1977). This solution requires NCS controls on process vessel and product solution tank diameters. Aqueous solutions are assumed to be optimally moderated, so control of the solution geometry is necessary for NCS to ensure desired material throughput can be maintained. The subcritical tank diameter (of infinite length and fully water reflected) for 5.0 wt. % ²³⁵U in aqueous UO₂F₂ solution is 20.1 cm (7.9 in.) (American National Standards Institute, 2014). For uranium enriched to 3.0 wt. % ²³⁵U, the subcritical tank diameter increases to 37.4 cm (14.7 in.) (American National Standards Institute, 2014). Aqueous ammonia is added to the aqueous UO₂F₂ solution to create ammonium diuranate precipitate that is collected, dried and heated to produce UO₂. The AUC process is similar, except that ammonium carbonate is used as the precipitating agent, so similar approaches to control geometry to safe configurations are used.

UO₂ powder processes

After the UF₆-to-UO₂ conversion process is complete, the UO₂ powder is pressed into pellets for fuel assembly fabrication. Fig. 2 shows each step in the conversion of UO₂ powder to fuel assemblies. During this process, the UO₂ powder must be kept dry (moderation control). Fissile powders can easily mix with moderators, e.g., water, oil, etc., and flow into unfavorable configurations, resulting in NCS concerns. Keeping UO₂ powder dry precludes any reduction in the critical mass below that of the subcritical limit for UO₂ powders at full density, spherical geometry, less than 1.5 wt. % water, and full water reflection, which is 32.3 kg of ²³⁵U (American National Standards Institute, 2014). The UO₂ powder is then blended to ensure uranium enrichment uniformity, compensating for the mixing of different batches with slight variations in enrichment (Knief, 1992). NCS at this stage involves limits on the mass, moderation and geometry parameter controls (blender shape/geometry) during processing. Hydrogenous “pore former” additives are blended with the powders to provide for porosity control during the final sintering process later on, and this hydrogenous material is taken into account for determining mass limits and geometry controls. NCS for the step to precompact the UO₂ powder to a low-density solid involves controlling the mass and geometry parameters while NCS for the next step, powder granulation to ensure uniform consistency, relies on mass and volume (hopper size) control.

Pellet operations

Fig. 2, steps 6-11, involve pressing powders into pellets to prepare for fuel assembly fabrication (pressing, sintering, grinding, washing/inspection, pellet loading and assembly fabrication). NCS control is maintained during the pellet manufacturing process

by using safe geometry transfer hoppers and powder lines and also by using passive engineered controls for conveyors and furnace boats which limiting the pellet stacking below a subcritical slab thickness. This subcritical slab thickness is about 10 cm (4-in) thick and is the primary NCS limit applied to processing, transport and in-process storage. A 10-cm-thick water-reflected slab is subcritical for dry UO_2 full density powders up to an enrichment of 5.0 wt. % ^{235}U (see Fig. 25 by Paxton and Pruvost (1986)). One of the implementation methods for this slab thickness control is a molybdenum furnace boat that is open on the top and filled with UO_2 pellets before and after the sintering process and will remain subcritical even flooded with water during a credible abnormal condition. Pellet sintering consolidates the powder particulate to result in a denser pellet. The resulting dimensions are intentionally larger, and the pellet diameters must be ground to the exact dimensions, which results in the generation of UO_2 powder, which remains subcritical due to favorable geometry equipment. Engineered controls preclude the stacking of pellets during operations (limitation on mass), ensuring pellet tray physical spacing (limitation on neutron interaction) and perforating the trays so water cannot accumulate in an abnormal condition (limitation on moderation). After the pellets are fabricated and ground to final dimensions, the pellets are washed, dried, and inspected. Water or air is used to remove impurities that may be present and then the pellets are dried in an oven to remove excess moisture. During inspection, each pellet is carefully inspected for defects prior to moving to the fuel rod fabrication process. For this step, NCS is ensured by using favorable geometry equipment and spacing (interaction) controls on pellet trays.

Loading UO_2 pellets into fuel rods and assemblies

The completed fuel pellets are loaded into tubes made of suitable cladding materials, such as zirconium alloy or stainless steel, then the tubes are sealed, charged with helium, and inspected. Subcritical slab geometry ensures subcriticality during fuel rod fabrication activities, even fully flooded with water. Collections of rods that need to be stored over time are put into metal horizontal storage boxes with covers in spaced arrays limited to a subcritical slab height (Knief, 1985). Completed fuel rods are about 4.3 m (~14 ft.) long (Knief, 1985).

Fuel assembly handling, storage, and transportation

Fresh fuel assembly handling, storage, and transportation require NCS controls derived from an NCS evaluation to ensure normal and credible abnormal conditions are subcritical. An NCS consensus standard is available that provides guidance on these operations with LWR fuel assemblies outside reactors (American National Standards Institute, 2009).

Rods are assembled into rectangular arrays of various sizes, ranging from 7×7 for older boiling water reactor designs to 17×17 for some pressurized water reactor designs. Once assembled, the fuel assemblies, or bundles, are handled carefully and require NCS controls to prevent water flooding (moderation control) and neutron interaction (spacing requirements). Several fuel bundles, two for some PWR bundle designs, can achieve criticality with optimum side-by-side spacing and full water flooding (Knief, 1985). A prudent NCS control for fuel assembly operations (assembly, cleaning, and inspection) typically restricts operations to one fuel bundle at a time, as a single bundle is they are subcritical when flooded by water. After the fuel assemblies are inspected, the fresh fuel assemblies are placed in storage racks designed to provide safe spacing between fuel assemblies (interaction control) and to preclude the accumulation of water near the fresh assemblies (moderation control). The transportation of fresh LWR fuel assemblies is accomplished by loading them into shipping containers for transport to a nuclear power plant. The shipping containers used for transportation activities in the U.S. are certified via U.S. Nuclear Regulatory Commission and US Department of Transportation regulations, 10 CFR Part 71 (Office of the Federal Register National Archives and Records Administration, 2020a) and 49 CFR Part 173 (Office of the Federal Register National Archives and Records Administration, 2020b). The packaging certification process in the U.S. requires the shipping package to be designed to withstand all Normal Conditions of Transport (NCT) and Hypothetical Accident Conditions (HAC) during transport operations. Based on the package design, package testing, number of packages, and proposed payload (in this case LWR fuel assemblies), a Criticality Safety Index can be derived to ensure packages will remain subcritical under NCT and HAC conditions. At the reactor site, LWR fuel assemblies are handled and stored as they were at the fuel fabrication facility. They are removed from the shipping containers and placed into storage racks or into water pool storage. The storage racks or pool storage locations may contain neutron poisons (absorption), such as gadolinium or boron, to provide additional safety margin during storage and handling. When the reactor core is loaded, fuel assemblies are removed from their storage racks one at a time and loaded into their core positions. Subcriticality of the core is assured by insertion of control and safety rods and, in PWR, adding soluble boron to the water.

Spent fuel reprocessing

Spent fuel can be reprocessed to recover unused fissile constituents from the spent fuel and to separate and remove fission products. Recovering the unused ^{235}U and the plutonium (^{239}Pu) produced by in-reactor neutron absorption in ^{238}U from the fuel allows reuse of these materials. Recovered uranium can be sent to an enrichment facility for further enrichment. The recovered ^{239}Pu can be blended with the uranium to make mixed oxide fuel (MOX). The separated fission products are disposed as waste. Spent fuel reprocessing is not currently part of the fuel cycle in the U.S. but is utilized in France, United Kingdom, Russia, and Japan. Spent fuel reprocessing involves the following steps, all of which require NCS control and guidance:

- Spent fuel transportation to a reprocessing facility.
- Spent fuel receipt, handling and interim storage.
- Fuel assembly disassembly and shearing operations.
- Dissolution of the spent fuel rod segments in nitric acid.
- Separation of fissionable materials (U and Pu) from aqueous solutions.
- Separation of heavy metals, fission products, and transuranic waste from the solution.
- Product preparation, handling, storage and transportation.
- Waste preparation, handling storage and transportation.

Spent fuel is transported in specially designed shielded casks that meet transportation safety regulations for transporting hazardous materials. These casks have been designed to prevent a criticality accident due to water intrusion and neutron interaction with other fuel, prevent the loss of any of the radioactive material, and to provide shielding and heat dissipation during transportation activities. NCS during spent fuel receipt, handling and interim storage is assured by handling assemblies in much the same manner as if they were fresh fuel, although the radiological hazards tend to outweigh the NCS hazards with spent fuel.

Fuel disassembly and shearing operations involve removing the individual fuel rods from the fuel bundles and shearing the rods into small segments (cladding and fuel pellet fragments) to facilitate efficient dissolution. Typically, NCS is considered with a limit of one spent LWR fuel assembly at a time for disassembly and shearing operations. After the fuel cladding is removed, the fuel segments are then dissolved in nitric acid to create an aqueous solution of spent fuel constituents (fissile and nonfissile actinides and fission products) and cladding materials. NCS control is essential during the dissolution stage because the combination of heterogeneous fuel pieces and fuel solution can be more reactive than the fuel assembly or aqueous solution separately (Knief, 1985). To allow a high throughput of sheared spent fuel dissolution the dissolver must be large enough to ensure complete and efficient dissolution operations can be performed, which is counter to NCS practice to reduce vessel diameter wherever possible. Because dissolver size is an NCS concern with fissile materials present, some dissolver tanks have been constructed with an annular geometry to increase neutron leakage and, consequently, to increase critical mass. Dissolved neutron poisons, such as cadmium, gadolinium, or boron either in the fuel or added to the dissolver will increase the critical mass, consequently increasing the safety margin, of the system.

After the fuel is dissolved, the fission products are separated from the uranium and plutonium present in the aqueous solution via various processes discussed by Taylor (2021). The product stream containing uranium and plutonium is sent for uranium and plutonium separation processing and the fission products and soluble poison are sent for waste processing. Soluble poisons in the aqueous solutions are no longer required for criticality control in the product stream. Criticality controls in the product stream are typically limitations to fissile material concentration and favorable equipment geometry. Further, tanks are typically small diameter with annular features to increase neutron leakage in the system. Further, the columns of these small diameter tanks for solution storage are typically spaced from each other such that neutron interaction between tanks is minimized. Uranium and plutonium product materials are converted to uranium oxide, plutonium oxide, or mixed oxide and can be shipped using a certified shipping container to fuel fabrication or enrichment facilities for further processing to recycle the material into LWR fuel.

High-activity, intermediate-activity and low-activity wastes from reprocessing are typically staged or stored in large volume vessels with fixed neutron poisons (neutron absorbing plates or tubes) or soluble neutron poisons, small-diameter tanks (favorable geometry), slab tanks (favorable geometry), or annular tanks (favorable geometry). These waste materials usually have no further use and need to be processed for safe long-term storage as liquid waste or dried and vitrified in stable form.

Spent fuel handling and storage

Fuel assemblies are resident in the core of an LWR for about 5–6 years. At end of life, the fuel assemblies are removed from the core and transported under water one assembly at a time to a spent fuel pool for interim storage for a few years. This time period allows the fission products to decay and for the assemblies to cool down sufficiently for other storage options. Typically, about 80% of the ^{235}U in the fuel assemblies is consumed during reactor operations; however, other fissile isotopes, such as ^{239}Pu , created from neutron absorption by ^{238}U are present in the spent fuel. Spent fuel pools are large, steel-lined, concrete water pools that are designed specifically to cool the spent fuel stored there. They are about 13.3 m (40 ft) deep to allow for attenuation of radiation. NCS is challenged if the fuel assembly is dropped (loss of fuel assembly geometry) or if the assembly is misplaced in the pool (storage array geometry change).

Because the U.S. has no commercial reprocessing facility, there has been a need to increase spent fuel storage capacity. NCS concerns with increasing spent fuel storage capacity in pools can be addressed by double tiering or stacking the fuel assemblies vertically (interaction as primary NCS control). Or boric acid can be added to the water (neutron absorption) allowing capacity increase by reducing the necessary spacing between the fuel assemblies in the pool. Solid neutron absorbers (neutron absorption) can be added to spent fuel storage racks to significantly increase storage capacity as well.

Because spent fuel is less neutronically reactive than fresh fuel, NCS evaluations for these systems can take advantage of a consensus standard for burnup credit for LWR fuel that accounts for reactivity effects of fuel burnup in a UO_2 -fueled LWR (American National Standards Institute, 2008). Burnup credit can be applied by estimating the fission product inventory in the spent fuel using computational tools such as ORIGEN (Rearden, 2016) and including that inventory in criticality calculations. Spent fuel contains fission products that can absorb neutrons from the overall system and increase nuclear criticality safety.

After the spent fuel has been stored for a few years in the spent fuel pool, the fuel assemblies can be removed from the pool storage racks and loaded into dry-storage casks at the reactor site. The fuel is loaded into a sealed steel cask that has an inert atmosphere. There are various dry storage cask system designs. With some designs, the steel cylinders containing the spent fuel assemblies are placed vertically in a concrete vault; other designs orient the cylinders horizontally. The concrete vaults provide the radiation shielding and are designed to ensure cooling sufficient to keep fuel at safe storage temperatures. Other cask designs orient the steel cylinder vertically on a concrete pad at a dry cask storage site and use both metal and concrete outer cylinders for radiation shielding. (United States Nuclear Regulatory Commission, 2019) Each cask contains 24–72 spent fuel assemblies, depending on the type of the fuel assembly, and NCS is ensured by spacing the individual casks, limiting water (moderation control), the use of fixed neutron poisons such as boron (absorber control), and limiting the number of assemblies in the storage design (mass control). Fuel assemblies can be stored long term in casks, or the fuel can be moved via approved shipping containers to long-term cask storage facilities.

The Onkalo spent nuclear fuel repository in Finland is the only high-level spent fuel repository to be operational in the near future (early 2020s) (Posiva Oy, 2020). Despite the lack of spent fuel repositories, NCS is a major factor in the transportation and storage strategy for a national repository. For spent fuel transportation, a variety of highly robust shipping containers for over-the-road and rail transport have been designed for shipping spent fuel to a repository. These shipping containers are designed in accordance with applicable regulations to withstand both NCT and HAC during transportation activities. NCS is also considered for pre-closure repository activities that include shipping and receiving operations, repackaging into long-term storage containers, and placement into the repository storage locations. Pre-closure NCS controls involve mass controls on the number of casks or fuel assemblies allowed to be handled at one time or limits on the number items stored in a location. NCS for cask storage involves limits on the spacing between casks to keep neutron leakage as high as practical (interaction). Post-closure activities include the long-term storage of the spent fuel and potential long-term retrieval operations. NCS for long-term storage considers burnup credit for the presence of fission product neutron absorbers to allow for more dense fuel assembly storage (interaction control). The use of robust container degradation over the years requires a robust storage container design to preclude the intrusion of water (moderation control) over time to minimize the risk of criticality after a repository has closed.

Nuclear criticality safety of research reactor fuels

There are no NCS concerns for an operating research reactor. However, NCS concerns arise when fresh fuel must be handled or removed from the core. Cole, et al., (2021) provides some background on research reactor fuel materials. Some research reactors are fueled with high enriched uranium (uranium with 93 wt. % ^{235}U), although the ^{235}U enrichment in most research reactors is 20% or lower. NCS is applied for fresh fuel and spent fuel handling. The fresh research reactor fuel would be analyzed for NCS and would consider controls on interaction (fuel spacing) and mass (one fuel assembly, fuel plate, or fuel item to be handled at a time). Spent fuel also has criticality concerns in the storage, handling and transportation steps of life and would likely involve NCS controls interaction (spacing), absorption (introduction of neutron poisons or burnup credit due to fission product absorbers present), and mass (number of fuel assemblies in a pool or storage cask). If stored fuel is to be spaced closer together for some reason, fixed poisons can be used in the storage locations to decrease neutron interaction, which makes the configuration safer from an NCS standpoint.

NCS with GEN-IV reactors

NCS with respect to the latest GEN-IV reactor designs (Stanculescu, 2021) such as Very High Temperature Reactors, Pebble Bed Modular Reactor, Molten Salt Reactors, Gas-cooled Fast Reactor (GFR), Sodium-cooled Fast Reactors (SFR), and Lead-cooled fast reactors (LFR) is applied similarly as for LWRs. The GFR, SFR, and LFR concepts use a predominately fast neutron spectrum, rather than a thermal neutron spectrum. In any case, NCS for the fuel cycles supporting these concepts is handled in the same way as to those processes for the LWR fuel cycle. The ANSI/ANS-8.1 standard (American National Standards Institute, 2014) requires that process analysis be performed on any process operation that involves fissionable materials outside of reactors. This process analysis requires close identification and analysis of the normal and credible abnormal conditions for processes involved with the processing, handling, storage, and transportation of the fissile materials present. The processes of interest (e.g., enrichment, fuel fabrication and handling), will each require NCS limits for controls on the NCS parameters (mass, absorption, geometry, interaction, concentration, moderation, enrichment, reflection, and volume) that will be similar to those needed for other, similar fuel cycle activities. For example, if a new reactor design considers a higher fuel enrichment of 20 wt. % ^{235}U rather than ~ 5 wt. % ^{235}U (typical for LWRs), this will result in more restrictive limits (larger spacing between fissile materials to increase leakage and decrease interaction) on NCS controls. Regardless, NCS is applied to a particular process in a similar way despite the differences in fissile materials and process environments in different fuel cycles.

Summary

NCS is inherently necessary for all fuel cycles involving the handling, processing, transportation, and storage of fissile isotopes (^{233}U , ^{235}U , and ^{239}Pu) to protect workers and the public. The discussion in this article has focused on those parts of the LWR

fuel cycle and described similar applications to new fuel cycle activities proposed with GEN-IV Reactor concepts. Those operations with very low fissile content, very small concentration or ^{235}U enrichment of less than about 1.0 wt. % ^{235}U have fewer NCS concerns than with operations with higher concentrations and enrichments for the LWR fuel cycle, research reactor fuel, or proposed GEN-IV advanced reactor fuel cycles. NCS fundamentals and background information were provided to understand the NCS hazards associated with fuel cycle processes to ensure all operations, normal and credible abnormal, remain subcritical to ensure facility workers and the public are safe from the consequences of a criticality accident. Consensus standards for NCS are available for use to assist NCS engineers and operations staff during the design, operation, and modification of hands-on fissile processes.

Introduction

Oxide ceramic nuclear fuels were introduced in the 1950s and are still the most widely used fuel types in present-day commercial reactors. Among the unique features that qualify these compounds for nuclear fuel applications are their high melting point, high retention of fission products thanks to the open crystal structure, and highly variable oxygen-to-metal ratio that can shift to accommodate fuel chemistry changes with burnup, resulting in excellent resistance to radiation damage. Other advantages of oxide nuclear fuels include inertness to many coolants, prolonged irradiation with low swelling, and a relatively low fabrication cost. Oxide ceramic fuels include uranium dioxide (UO_2) and uranium-plutonium mixed-oxide ((U, Pu) O_2 , or MOX) fuels. UO_2 has been used in the light-water reactor (LWR) fuel rods (Reeve, 1975; Olander, 1976, 2009) and high-temperature gas-cooled reactor (HTGR) fuel particles (Reeve, 1975; Kania et al., 2013). MOX has been used in LWR and fast breeder reactor (FBR) fuel rods (Reeve, 1975; Olander, 1976, 2009; Waltar et al., 2012). Mixed thorium-uranium oxide ((Th, U) O_2) and thorium-plutonium oxide ((Th, Pu) O_2) are also ceramic compounds that have been used as nuclear fuels in HTGRs and LWRs (Reeve, 1975; IAEA, 2005).

The notable shortcomings of oxide ceramic fuels are their low uranium density and low thermal conductivity. UO_2 has a theoretical density (TD) of about 10,970 kg/m³, and its uranium density of about 9670 kg/m³ is approximately half that of uranium metal. The lower the uranium density, the lower the amount of fissile material and the maximum attainable length of the reactor operation cycle. Poor thermal conductivity results in high fuel centerline temperatures and high temperature gradients across the fuel element to extract sufficient fission heat per unit of fuel to make electric power production economical. At high temperatures, solid-state reactions proceed at rates adequate to produce significant changes in material properties during the fuel lifetime in the reactor. Thermal stresses resulting from the steep temperature gradient across the fuel pellet cause the fuel to crack in low-temperature regions or deform plastically in high-temperature zones. The temperature gradient also drives pore migration and redistribution of fuel constituents, such as oxygen, plutonium, and fission products, from their initial concentration profiles. However, pellet cracking can be allowed inside a structural metal cladding. The low thermal conductivity is compensated for by a high melting point of about 3100 K with an absence of phase changes up to the melting point and by the acceptable irradiation behavior of oxide ceramic fuels (Reeve, 1975; Olander, 1976).

Non-oxide ceramics, such as uranium and mixed uranium-plutonium carbides (UC and (U,Pu)C) and nitrides (UN and (U,Pu)N), have also been investigated for nuclear fuel applications (Reeve, 1975; Blank, 1988; Streit and Ingold, 2005; Terrani et al., 2020), motivated by advantages over oxide fuels that include higher uranium density and higher thermal conductivity. The uranium density of uranium monocarbide (UC) is 12,970 kg/m³, and that of uranium mononitride (UN) is 13,520 kg/m³. These values are about 35–40% higher than the uranium density of UO_2 . For this reason, non-oxide ceramic fuels are also referred to as dense ceramic fuels (Blank, 1988). Both uranium carbides and nitrides are candidates for application in FBRs (Crawford et al., 2007; Chandar et al., 2020). Moreover, uranium nitride is considered for application as nuclear fuel for future space reactor systems, as it exhibits good thermal and irradiation behavior as well as compatibility with many candidate space reactor coolants and structural materials (Hayes et al., 1990a). Finally, a solid solution of uranium carbide and nitride (U(C,N)) that is rich in the latter is being used to fabricate fuel particles currently under testing for use in LWRs and advanced reactors (Terrani et al., 2020).

UC exhibits a metallic electronic structure due to the overlaps of f-orbitals. Hyperstoichiometric UC_{1+x} contains a precipitate of UC_2 or U_2C_3 . For hyperstoichiometric uranium carbides, the metallic character persists, and the C–C bonds are covalent like in

graphite. The U-4f core levels do not change strongly with increasing carbon content, and the U-5f electrons are predominantly itinerant (Manara and Agarwal, 2020). Hypostoichiometric UC_{1-x} contains a grain boundary distribution of uranium metal, which leads to unfavorable in-reactor swelling behavior. The in-reactor behavior of (U,Pu)C is relatively similar to that of UC (Reeve, 1975).

In this article, we provide an overview of the main properties of oxide ceramic fuels UO_2 and MOX, as well as dense ceramic fuels UC and UN. In particular, thermal properties are dealt with in “Thermal properties” section, and mechanical properties are summarized in “Mechanical properties” section. For brevity, mixed uranium-plutonium carbides and nitrides, and thorium-based oxide ceramic fuels are not covered here in detail. Finally, this work is limited to fresh (i.e., zero burnup) fuel properties. Therefore, changes in properties with burnup and burnup-dependent phenomena, such as fuel densification and fission-product swelling, are not included in this article. Ceramic fuel irradiation performance is discussed by Cantonwine and Rand (2021).

Thermal properties

The thermal properties of ceramic fuel compounds addressed in this section include thermal conductivity, melting point, and specific heat capacity. Each subsection consists of an introduction and definition for the corresponding property, followed by examples of correlations used in computational analyses. A detailed discussion on the physical understanding of material properties is beyond the scope of this article. However, to lead into the mathematical formulations presented in the following, we mention here that the thermal conductivity of the considered materials has main contributions due to lattice vibrations (phonon component) and free electrons (electronic component), and the heat capacity is mainly a consequence of the vibrations of the atoms in the lattice.

Thermal conductivity

The thermal conductivity of UO_2 and MOX depends on temperature, fuel density, oxygen to metal (O/M) ratio, and additive content, in addition to burnup. The basic form used to represent the thermal conductivity of ceramic oxide fuels includes a lattice vibration (phonon) term and an electronic term, i.e.,

$$k_p = k_{ph} + k_{el} \quad (1)$$

where k_p (W/m K) is the thermal conductivity at a certain fuel density (ρ), k_{ph} the phonon term, and k_{el} the electronic term. The first term is typically of the form

$$k_{ph} = \frac{1}{A + BT} \quad (2)$$

where A (mK/W) is a parameter that relates to phonon scattering from lattice impurities and defects, B (m/W) a parameter that takes into account phonon-phonon interactions, and T (K) the temperature. The deviation from stoichiometry and dopants such as gadolinia (Gd_2O_3) affect the thermal conductivity in a manner that can be taken into account through additional terms in Eq. (2). Moreover, burnup accumulation creates fission product impurities in the lattice, which affect the phonon term. The electronic term is generally of the form

$$k_{el} = f(T)\exp(-C/T) \quad (3)$$

where f (W/m K) is a function of temperature and C (K) is an empirical constant.

Correlations for the thermal conductivity of UO_2 and MOX used in fuel behavior calculations are available, e.g., in Harding and Martin (1989), Massih et al. (1992), Lucuta et al. (1996), Pihlatie (1999), Ronchi et al. (1999), Duriez et al. (2000), and MATPRO (2003). An expression for the thermal conductivity of fresh UO_2 , given by Harding and Martin (1989) and also used by Lucuta et al. (1996), is

$$k_{100} = \frac{1}{0.0375 + 2.165 \times 10^{-4}T} + \frac{4.715 \times 10^9}{T^2} \exp\left(-\frac{16361}{T}\right) \quad (4)$$

where k_{100} (W/m K) denotes the thermal conductivity for fuel at 100% TD. Other correlations account for the effect of Gd_2O_3 content in UO_2 , such as the one from Massih et al. (1992).

$$k_{100} = \frac{1}{0.1149 + 2.48 \times 10^{-4}T + 1.1599g} + 1.216 \times 10^{-2} \exp(1.867 \times 10^{-3}T) \quad (5)$$

where g (wt. fraction) is the Gd_2O_3 content.

A correlation for the thermal conductivity of fresh MOX fuel is the one from Duriez et al. (2000).

$$k_{95} = \frac{1}{0.035 + 2.85x + (2.86 - 7.15x)10^{-4}T} + \frac{1.689 \times 10^9}{T^2} \exp\left(-\frac{13520}{T}\right) \quad (6)$$

where k_{95} (W/m K) denotes the thermal conductivity for fuel at 95% TD and $x = 2 - O/M$ is the deviation from stoichiometry, with O/M being the oxygen to metal ratio. Eq. (6) is based on data from MOX samples with low Pu content in the range 0.03–0.15 wt. fraction (Duriez et al., 2000).

Furthermore, a correction for the effect of sintering pores (and for fission gas bubbles in irradiated fuel) is introduced. In case of the closed porosity formed by isolated spherical pores, the Maxwell-Eucken formula can be used

$$k = k_{100} \left(\frac{1-p}{1+\beta p} \right) \quad (7)$$

where k (W/m K) is the thermal conductivity, p (–) the fractional porosity, and $\beta = 0.5$.

The thermal conductivity of UC involves dependencies that include temperature, carbon to uranium ratio (C/U), oxygen impurities, and grain size (Manara and Agarwal, 2020). A simple analytical relation proposed by Matzke (1986) and reported by Manara and Agarwal (2020) that can be used for modeling purposes is

$$k = \begin{cases} 20 & \text{for } T < 773K \\ 20 + 1.3 \times 10^{-3}(T - 773) & \text{for } T \geq 773K \end{cases} \quad (8)$$

where k (W/m K) is the thermal conductivity. Oxygen impurities lead to a decrease of the thermal conductivity of UC that can reach up to a factor of 2 for 15 at.% O (Holleck and Kleykamp, 1987). Also, the thermal conductivity of UC was reported to increase with the grain size at equal porosity (Holleck and Kleykamp, 1987).

The thermal conductivity of UN can be estimated with the correlation (NASA GRC, 2019)

$$k = \left(\frac{1-p}{1+p} \right) \begin{cases} 22.55T_r^{0.3845} & \text{for } 10 \leq T \leq 2025K \\ 29.58 & \text{for } 2025 < T \leq 2500K \end{cases} \quad (9)$$

where k (W/m K) is the thermal conductivity, p (–) the fractional porosity and $T_r = T/1000$ the reduced temperature. Eq. (9) is valid for $0 \leq p \leq 0.2$ and $10 \leq T \leq 2500$ K. Experimental evidence shows that the increase in the proportion of plutonium content in a mixed uranium-plutonium nitride fuel significantly reduces its thermal conductivity (Arai et al., 1993).

Thermal conductivity correlations for UO_2 , MOX, UC, and UN corresponding to Eqs. (4), (6), (8), (9), respectively, are plotted in Fig. 1 (a semi-log plot). Experimental data (Vlahovic et al., 2018; Duriez et al., 2000; De Coninck et al., 1975; Kurosaki et al., 2000) are also reported for comparison. Only undoped fuel is considered in Fig. 1. The plot highlights the significantly higher thermal conductivity of dense ceramic fuels UC and UN compared to oxide ceramic fuels UO_2 and MOX. Also, there is considerable

Fig. 1 The thermal conductivity of fresh stoichiometric UO_2 , MOX, UC, and UN with experimental data from Vlahovic et al. (2018), Duriez et al. (2000), De Coninck et al. (1975), and Kurosaki et al. (2000). For UO_2 , Eq. (4) has been used along with Eq. (7) to obtain the thermal conductivity at 95% TD, consistent with the experimental data from Vlahovic et al. (2018). For UC, the experimental data refer to samples with approximately 99–100%TD (De Coninck et al., 1975), while Eq. (8) is not associated with a specific density in (Manara and Agarwal, 2020).

dispersion in the experimental data for UO_2 and MOX, even in the limited database shown in Fig. 1. Significant dispersion can also be appreciated in the reported data for UC and UN. The uncertainty in the fuel thermal conductivity is one of the most important sources of uncertainty in the thermal analysis of nuclear fuel (Bouloré et al., 2012). Uncertainties can arise from three main sources in engineering modeling: (1) model input uncertainties due to the nature of the experiments providing the data (e.g., uncertainties in the physical geometry, experimental settings, biases, etc.), which are typically reported by the experimentalists with error bars; (2) model solution uncertainties, corresponding to discrepancies between the numerical approximations and the expected results; and (3) model form uncertainties, related to the accuracy of the mathematical model in representing the real-life behavior of the parameter of interest. An analyst can perform uncertainty quantification studies by propagating those uncertainties in the system to establish confidence in the response values.

Melting point

The solidus in the phase diagram of the fuel material represents the lowest temperature with an indication of melting and is loosely referred to as the melting point (Olander, 1976). The melting point of the fuel material is needed to define the limiting power of a fuel element.

The melting point of fresh stoichiometric UO_2 is in the range of 3073–3153 K (Hausner, 1965; Lyon and Baily, 1967; Brassfield et al., 1968; Latta and Fryxell, 1970; Olander, 1976). However, it is lower in non-stoichiometric $\text{UO}_{2\pm x}$. Also, mixed uranium-plutonium oxides, i.e., MOX fuels, melt at lower temperatures than pure UO_2 . Since UO_2 and PuO_2 form nearly ideal solid solutions, the melting point of the mixture varies smoothly from that of UO_2 to that of PuO_2 (Olander, 1976). Also, irradiation and the consequent buildup of fission-product impurities affect (reduce) the melting point of the fuel material (Olander, 1976). Correlations for the melting point of UO_2 and MOX as a function of PuO_2 content and burnup are given in the MATPRO material property library (MATPRO, 2003). According to MATPRO (2003), the melting temperature (solidus) of fresh stoichiometric UO_2 and mixed UO_2 and PuO_2 (MOX) is given as

$$T_m = 3113 - 5.414 \times 10^2 \omega + 7.468 \times 10^1 \omega^2 \quad (10)$$

where ω (wt. fraction) is the PuO_2 content. For irradiated fuel, a negative term proportional to burnup is included (MATPRO, 2003). Eq. (10) is based on the value of 3113 K for the melting temperature of UO_2 (Lyon and Baily, 1967; Brassfield et al., 1968) and the phase diagram for stoichiometric (U,Pu) O_2 from Brassfield et al. (1968). Note that, according to Lyon and Baily (1967), an uncertainty of ± 20 K is associated with the measurement for the value of 3113 K for the melting temperature of UO_2 .

The melting temperature of stoichiometric UC has been reported as $T_m = 2780$ K (Manara and Agarwal, 2020). Stoichiometric UC is stable from room temperature to its melting point. However, at temperatures greater than 1400 K UC can exist in both hypo-stoichiometric and hyperstoichiometric forms (Manara and Agarwal, 2020).

The vapor or decomposition pressure of UN is often experimentally studied rather than the melting point in the literature because UN melts only under high nitrogen partial pressures, and its decomposition occurs at lower pressures (both fuel melting and decomposition are undesirable conditions for nuclear fuel applications). To determine safety margins for UN fuel elements in engineering analyses, the temperature-pressure relationship for the melting or decomposition of UN is required. A correlation for the melting or decomposition temperature of UN valid for nitrogen pressures between 1×10^{-13} and 7.5 atm was developed in Hayes et al. (1990c), and reads

$$T_{m,d} = 3035.0(P_{N_2})^{0.02832} \quad (11)$$

where $T_{m,d}$ (K) is the melting or decomposition temperature and P_{N_2} (atm) is the nitrogen vapor pressure over UN. The latter is estimated by (Hayes et al., 1990c)

$$\log_{10}(P_{N_2}) = 1.8216 + 1.882 \times 10^{-3}T - 23543.4/T \quad (12)$$

for $1400 \leq T \leq 3170$ K. Eq. (12) is solved for temperature at a given nitrogen vapor pressure to estimate the temperature at which either melting or decomposition of UN occurs.

Specific heat capacity

Accurate knowledge of the specific heat capacity of the fuel material is required for assessment of fuel behavior under transient conditions, where the thermal diffusivity (which depends on the thermal conductivity, fuel density, and specific heat capacity) determines the time dependence of the temperature (Olander, 1976). The stored energy or enthalpy is also important in reactor transient analysis (e.g., reactivity-initiated accidents, or RIAs) because the severity of the transient is greatly affected by the initial stored energy of the fuel.

In the MATPRO library (MATPRO, 2003), an empirical correlation for the specific heat capacity at temperature T of solid UO_2 and PuO_2 is given in the form

$$c_p = \frac{K_1 \theta^2 \exp(\theta/T)}{T^2 [\exp(\theta/T) - 1]^2} + K_2 T + \frac{Y K_3 E_D}{2RT^2} \exp\left(-\frac{E_D}{RT}\right) \quad (13)$$

Table 1 Values for the parameters in the specific heat capacity and enthalpy correlations from MATPRO (2003), Eqs. (13) and (14).

	K_1 (J/kg K)	K_2 (J/kg K ²)	K_3 (J/kg)	θ (K)	E_D (J/mol)
UO ₂	296.7	2.43×10^{-2}	8.745×10^7	535.285	1.577×10^5
PuO ₂	347.4	3.95×10^{-4}	3.860×10^7	571.000	1.967×10^5

and the specific enthalpy at temperature T is derived by integrating Eq. (13) with respect to temperature, yielding

$$h = \frac{K_1 \theta}{\exp(\theta/T) - 1} + \frac{K_2 T^2}{2} + \frac{Y K_3}{2} \exp\left(-\frac{E_D}{RT}\right) \quad (14)$$

where c_p (J/kg K) is the specific heat capacity, h (J/kg) the specific enthalpy, $Y = O/M$ (–) the oxygen-to-metal ratio, R (8.314 J/mol K) the universal gas constant, θ (K) the Einstein temperature, and K_1 (J/kg K), K_2 (J/kg K²), K_3 (J/kg), E_D (J/mol) are constant parameters. The values for the parameters in Eqs. (13) and (14) relative to UO₂ and PuO₂ are reported in Table 1.

For a mixture of UO₂ and PuO₂ (MOX fuel), the specific heat capacity and specific enthalpy are evaluated as weighted averages of the contributions from each component (MATPRO, 2003)

$$c_{p,(U,Pu)O_2} = (1 - \omega)c_{p,UO_2} + \omega c_{p,PuO_2} \quad (15)$$

$$h_{(U,Pu)O_2} = (1 - \omega)h_{UO_2} + \omega h_{PuO_2} \quad (16)$$

where ω (wt. fraction) is the PuO₂ content.

The specific heat capacity of solid UC can be calculated as a function of temperature as (Manara and Agarwal, 2020)

$$c_p = 1.973 \times 10^2 + 1.012 \times 10^{-1} T - 7.352 \times 10^{-5} T^2 + 2.250 \times 10^{-8} T^3 - 2.435 \times 10^6 T^{-2} \quad (17)$$

Most of the U and Pu carbides show steep increase in heat capacities at temperatures above $0.6 T_m$, which is attributed to the formation of defects (Holley et al., 1984; Manara and Agarwal, 2020).

The specific heat capacity of UN can be evaluated by (NASA GRC, 2019)

$$c_p = \begin{cases} 2.784 \times 10^5 T_r^{2.168} / (1 + 91.91 T_r + 756.8 T_r^2 + 408.6 T_r^3) & \text{for } 5 \leq T \leq 293 \text{ K} \\ 2.14 \times 10^2 + 9.746 T_r + 1.718 \times 10^1 T_r^2 - 2.607 / T_r^2 & \text{for } 293 < T \leq 3000 \text{ K} \end{cases} \quad (18)$$

where $T_r = T/1000$ is the reduced temperature.

In Fig. 2, correlations for the specific heat capacity of UO₂, PuO₂, UC, and UN are compared to each other and to experimental data from (Kruger, 1968; Ronchi et al., 1993; Amaya et al., 2004; Moser and Kruger, 1967; Hayes et al., 1990c). Additionally, in Fig. 3, correlations for the enthalpy of UO₂ and PuO₂ are plotted along with experimental data from (Szwarc, 1969; Kruger, 1968). At moderate temperatures, the specific heat capacity of UO₂ is relatively similar to PuO₂. At higher temperatures (above ~2000 K), the specific heat capacity of UO₂ significantly differs from PuO₂. The specific heat capacity and enthalpy of (U,Pu)O₂ lie between the values for UO₂ and PuO₂. Lastly, specific heat capacities of UC and UN are comparable to each other and lower than the specific heat capacities of UO₂ and PuO₂, at least at temperatures below 2200–2600 K.

Mechanical properties

Mechanical properties of ceramic fuel compounds addressed in this section include thermal expansion, elasticity, plasticity, fracture strength, and creep. Each subsection consists of an introduction and definitions for the relevant properties, followed by representative values and correlations used in computational analyses.

Thermal expansion

With reference to thermal expansion, the thermodynamic property considered for the material is the coefficient of linear thermal expansion (CTE), which is defined as

$$\alpha = \frac{1}{l} \frac{dl}{dT} \quad (19)$$

where α (1/K) is the CTE and l (m) the length of the specimen.

The following empirical correlation has been recommended by Martin (1988) for the CTE of stoichiometric UO₂ and stoichiometric (U,Pu)O₂ in the solid phase

Fig. 2 The specific heat capacity of UO_2 , PuO_2 , UC , and UN with experimental data from Kruger (1968), Ronchi et al. (1993), Amaya et al. (2004), Moser and Kruger (1967), and Hayes et al. (1990c).

Fig. 3 The specific enthalpy of UO_2 and PuO_2 with experimental data from Szwarc (1969) and Kruger (1968). Data are given in terms of relative difference between the enthalpy values at temperature T and at 298 K.

$$\alpha_{\text{UO}_2} = \begin{cases} 9.828 \times 10^{-6} - 6.390 \times 10^{-10}T + 1.330 \times 10^{-12}T^2 - 1.757 \times 10^{-17}T^3 & \text{for } 273\text{K} \leq T \leq 923\text{K} \\ 1.1833 \times 10^{-5} - 5.013 \times 10^{-9}T + 3.756 \times 10^{-12}T^2 - 6.125 \times 10^{-17}T^3 & \text{for } 923\text{K} < T \leq 3120\text{K} \end{cases} \quad (20)$$

The effect of non-stoichiometry on the CTE of UO_2 is low, at least for $|O/M - 2| < 0.2$ (Martin, 1988; Baldock et al., 1966; MATPRO, 2003). It was established that Eq. (20) also describes the thermal expansion of solid hyperstoichiometric UO_{2+x} with

x values in the ranges 0–0.13 and 0.23–0.25 (Martin, 1988). Eq. (20) is valid for stoichiometric MOX with Pu content up to ~30% (Martin, 1988). For hypostoichiometric MOX, the CTE of $(\text{U,Pu})\text{O}_{2-x}$ can be evaluated as (Martin, 1988)

$$\alpha_{(\text{U,Pu})\text{O}_{2-x}} = \alpha_{\text{UO}_2} [1 + 3.9(\pm 0.9)x] \quad (21)$$

where α_{UO_2} is the CTE of stoichiometric UO_2 at the same temperature. For hyperstoichiometric MOX, Roth et al. (1967) found the following dependency of the CTE of $(\text{U,Pu})\text{O}_{2+x}$ on the deviation from stoichiometry, also taken up by Olander (1976).

$$\alpha_{(\text{U,Pu})\text{O}_{2+x}} = \alpha_{(\text{U,Pu})\text{O}_2} (1 - 5.1x) \quad (22)$$

where $\alpha_{(\text{U,Pu})\text{O}_2}$ is the CTE of stoichiometric $(\text{U,Pu})\text{O}_2$ of the same plutonium content at the same temperature. This relation was established for $1.94 < O/M < 2.01$ and only for a 20% PuO_2 – UO_2 mixture (Roth et al., 1967; Olander, 1976).

The following expression for the CTE of UC has been proposed in Manara and Agarwal (2020).

$$\alpha_{\text{UC}} = 10.08 \times 10^{-6} + 5.802 \times 10^{-9} \times (T - 273.16) \quad (23)$$

The CTE of UN in the range of $298 \leq T \leq 2523$ K has been given by Hayes et al. (1990a) as

$$\alpha_{\text{UN}} = 7.096 \times 10^{-6} + 1.409 \times 10^{-9} T \quad (24)$$

Correlations for the CTE of the fuel types considered here are plotted in Fig. 4.

Elastic constants

Like most other ceramics, polycrystalline UO_2 is a brittle material under normal conditions, i.e., at temperatures lower than about one half of the melting point (Olander, 1976). As stress is applied, a brittle substance deforms elastically, according to Hooke's law, until the critical stress value for fracture (fracture strength) is exceeded. For elastic deformation, the stress-strain curve is a straight line. The slope of the curve in a uniaxial tensile test is equal to Young's modulus of the material. The ratio of transverse contraction strain to longitudinal extension strain in the direction of the stretching force is Poisson's ratio of the material. The ratio of shear stress to shear strain is the shear modulus.

Young's modulus of oxide fuels is affected by the temperature, density and, to a lesser extent, oxygen-to-metal ratio and burnup of the fuel. Although published $(\text{U,Pu})\text{O}_2$ mixed oxide data are limited, it has been indicated that the addition of PuO_2 to UO_2 causes an increase in Young's modulus (MATPRO, 2003). The following correlation is given in MATPRO (2003) for Young's modulus of stoichiometric UO_2 below the melting temperature

$$E_s = 2.334 \times 10^{11} [1 - 2.752(1 - D)] [1 - 1.0915 \times 10^{-4} T] \quad (25)$$

where E_s (Pa) is Young's modulus and D (fraction of TD) the fuel density. For nonstoichiometric fuel or fuel that contains PuO_2 (MOX fuel), according to (MATPRO, 2003), Young's modulus below the melting temperature is described by

Fig. 4 Correlations for the linear thermal expansion coefficient of UO_2 and MOX, UC, and UN.

$$E = E_s \exp(-bx)[1 + 0.15\omega] \quad (26)$$

where E (Pa) is Young's modulus, b (–) is a parameter equal to 1.34 for hyperstoichiometric fuel or 1.75 for hypostoichiometric fuel, $x = 2 - O/M$ (–) is the deviation from stoichiometry, and ω (wt. fraction) is the PuO_2 content.

Correlations and experimental data for Young's modulus of UO_2 and MOX are reported in Fig. 5.

Poisson's ratio can be related to Young's modulus and the shear modulus as follows

$$\nu = \frac{E}{2G} - 1 \quad (27)$$

where ν (–) is Poisson's ratio, and G (Pa) is the shear modulus. Values between 0.306 and 0.320 have been reported for Poisson's ratio of UO_2 at room temperature (Wachtman et al., 1965; Padel and de Novion, 1969; Olander, 1976; MATPRO, 2003). Based on the effect of fuel porosity on Young's and shear moduli of UO_2 as determined by Marlowe and Kaznoff (1969), Olander (1976) gave the following formula for Poisson's ratio of UO_2 at room temperature as a function of porosity

$$\nu = 1.32(1 - 0.26p) - 1 \quad (28)$$

where p (–) is the fractional porosity.

For MOX fuel with 20% Pu content, a Poisson's ratio of 0.276 ± 0.094 at room temperature has been reported (Nutt et al., 1970; MATPRO, 2003; Sobolev, 2005).

Expressions for Young's modulus and Poisson's ratio of UC and UN at room temperature as a function of porosity have been determined experimentally by Padel and de Novion (1969). For UC, the expressions read

$$E = E_0(1 - 2.717p) \quad (29)$$

$$\nu = \nu_0(1 - 0.993p) \quad (30)$$

where $E_0 = 2.249 \times 10^{11}$ Pa and $\nu_0 = 0.288$ are the values for Young's modulus and Poisson's ratio, respectively, of UC at 100% TD (Padel and de Novion, 1969). For UN, the expressions read

$$E = E_0(1 - 2.307p) \quad (31)$$

$$\nu = \nu_0(1 - 1.313p) \quad (32)$$

where $E_0 = 2.668 \times 10^{11}$ Pa and $\nu_0 = 0.284$ are the values for UN at 100% TD (Padel and de Novion, 1969).

Fig. 5 Young's modulus of (A) UO_2 and (B) $(\text{U,Pu})\text{O}_2$ with a 20% Pu content with experimental data from Belle and Lustman (1978), Padel and de Novion (1969), Hall (1970), and Hirooka and Kato (2017).

Plasticity

At sufficiently high temperatures, even normally brittle materials such as UO_2 exhibit measurable amounts of unrecoverable or plastic deformation under applied stress before failure occurs (ductile behavior). The point on the stress-strain curve that indicates the limit of elastic behavior and the beginning of plastic behavior is the yield point, and the corresponding stress is the yield stress. The strains beyond the yield point are not recovered when the load is removed. The transition from brittle to ductile behavior occurs at a temperature characteristic of the material, called the ductile-brittle transition temperature or nil ductility temperature. In this regard, Olander (1976) identified three temperature regions for UO_2 :

1. A *brittle region* from room temperature to the ductile-brittle transition temperature. The latter is dependent on the strain rate imposed on the specimen during the test. It can be identified at about 1473 K for a strain rate of about 0.1 h^{-1} , based on test results by Canon et al. (1971).
2. A *semibrittle region* from the ductile-brittle transition temperature to the temperature above which purely ductile behavior is observed. The latter is estimated as 1673 K (Olander, 1976). A measurable plastic strain occurs before fracture, and yield stress can be determined. The ultimate strength of the material remains high.
3. A *region of complete ductility*, where the ultimate strength decreases rapidly with temperature and appreciable plastic deformation occurs before ductile fracture.

The distinction above has led to a model for the mechanical state of the fuel pellet during irradiation, with (i) an outer, colder region that is brittle and subject to cracking due to the thermal stresses set up by the temperature gradient; (ii) an intermediate region, which is strong and moderately ductile; and (iii) an inner, hot region that is easily subject to plastic deformation and is therefore not cracked (Olander, 1976).

UC is known to have good plasticity under load and at high temperature, which allows its fabrication by extrusion. The brittle-ductile transition occurs between 1273 and 1473 K, depending on deformation and grain size (Manara and Agarwal, 2020).

Fracture strength

The critical stress at which a specimen fails via fracture is called the fracture strength. Ductile materials have a fracture strength lower than the ultimate tensile strength (UTS) whereas, in brittle materials the fracture strength is equivalent to the UTS. The fracture strength and the yield stress are considered as independent temperature-dependent properties of the material. At temperatures where the fracture strength is lower than the yield stress, failure occurs in a brittle fashion, with no plastic flow prior to failure. At higher temperatures, yielding occurs at a lower stress than that required to induce fracture and, as a result, plastic deformation and ductile fracture are observed (Olander, 1976).

The correlation proposed in the MATPRO (2003) for the in-pile fracture strength of UO_2 as a function of temperature and fuel density reads

$$\sigma_f = 1.7 \times 10^8 \sqrt{1 - 2.62(1 - D)} \begin{cases} \exp[-1590/(8.314T)] & \text{for } 273 < T \leq 1000\text{K} \\ \exp(-1.590/8.314) & \text{for } T > 1000\text{K} \end{cases} \quad (33)$$

where σ_f is the fracture strength (Pa), and D (fraction of TD) is the fuel density. According to this model, a constant value for the fracture strength is used above 1000 K. This is based on the consideration that 1000 K is the lowest temperature at which plasticity has been observed in-pile (MATPRO, 2003). The transition from brittle to ductile material is accompanied by a discontinuity in the fracture strength and occurs at temperatures below the usual out-of-pile brittle-ductile transition temperature due to fission-induced plasticity (MATPRO, 2003). The value for the fracture strength above 1000 K in Eq. (33) is based upon theoretical considerations and out-of-pile data and applies to plastic UO_2 .

Fig. 6 shows the fracture strength of UO_2 as a function of temperature at varied fuel densities, according to Eq. (33). Experimental data are also shown. The significant scatter in the experimental data is evident.

Note that, when subjected to purely compressive loads, ceramics such as UO_2 are found to be far stronger than they are under tension. The compressive fracture strength of UO_2 is nearly an order of magnitude greater than the ultimate tensile strength obtained from bending tests (Olander, 1976). For application to fuel mechanical analysis, the tensile fracture strength is shown in Fig. 6 is the important one (Olander, 1976).

For UC, data are available for the transverse rupture strength and indicate a value of the order of 100 MPa for stoichiometric UC at room temperature (Rough and Chubb, 1960).

The fracture strength of UN has been reported as ~ 370 MPa at 1073 K (Feng et al., 2012). This value is about three times larger than that of UO_2 at the same temperature.

Creep

Creep is time-dependent plastic deformation. In general, the steady-state creep strain rate of oxide fuels depends on time, temperature, stress, fission rate, fuel grain size, density, and oxygen to metal ratio. The steady-state creep rate correlation for UO_2 given in MATPRO (2003) reads

Fig. 6 The fracture strength of UO₂ at 95% TD with experimental data from Burdick and Parker (1956), Roberts and Ueda (1972), Knudsen et al. (1960), Canon et al. (1971), Solomon (1972), and Katanic-Popovic and Petrovic (1973).

$$\dot{\epsilon}_S = \frac{(A_1 + A_2 \dot{F})}{(A_3 + A_4 D) G^2} \sigma e^{(-Q_1/T)} + \frac{(A_5 + A_8 \dot{F})}{(A_6 + A_4 D)} \sigma^{4.5} e^{(-Q_2/T)} + A_7 \sigma \dot{F} e^{(-Q_3/T)} \quad (34)$$

where $\dot{\epsilon}$ (s⁻¹) is the creep strain rate, $\dot{F}$ (fissions/m³ s) the fission rate, σ (Pa) the stress, R (J/mol K) the universal gas constant, D (fraction of TD) the fuel density, G (μ m) the grain size, and Q_1 and Q_2 are the activation energies given as (in cal/mol)

$$Q_1 = \frac{9000.0}{\exp\left(\frac{-20}{\ln(O/M-2)} - 8\right) + 1} + 36294.4 \quad (35)$$

$$Q_2 = \frac{10000.0}{\exp\left(\frac{-20}{\ln(O/M-2)} - 8\right) + 1} + 56431.8 \quad (36)$$

where O/M is the oxygen-to-metal ratio.

The correlation from MATPRO (2003) for the steady-state creep rate of MOX fuel reads

$$\dot{\epsilon}_S = \frac{(B_1 + B_2 \dot{F})}{G^2} \sigma e^{(-Q_3/T + B_3[1-D] + B_4 \omega)} + (B_5 + B_6 \dot{F}) \sigma^{4.5} e^{(-Q_4/T + B_7[1-D] + B_4 \omega)} \quad (37)$$

where ω denotes the PuO₂ content (wt. fraction).

Note that, in MATPRO (2003), a transition stress $\sigma_t = 1.6547 \times 10^7 / G^{0.5714}$ is introduced such that for $\sigma > \sigma_t$, σ is replaced by σ_t in the first term on the right hand side of Eqs. (34) and (37). The values for the parameters in Eqs. (34) and (37) are given in Table 2. Fig. 7 shows experimental data from the literature for the steady-state creep rates of UO₂ and MOX compared to model predictions corresponding to Eqs. (34) and (37), respectively.

For both UC and UN, the steady-state creep rate at high temperatures can be expressed in the form (Hayes et al., 1990b; Manara and Agarwal, 2020)

$$\dot{\epsilon}_S = A G^{-m} \sigma^n \exp\left(-\frac{Q}{RT}\right) \quad (38)$$

where A (1/s), m (–) and n (–) are constants, G (m) is the grain size, σ (MPa) the stress, Q (J/mol) the apparent activation energy, R (J/mol K) the ideal gas constant, and T (K) the temperature.

For UC, values $A = 4.36 \times 10^7$, $n = 2.4$, and $Q = 5.06 \times 10^5$ were reported in (Manara and Agarwal, 2020) with reference to Eq. (38). It was also noted that these values seem too uncertain to be used in fuel performance models (Manara and Agarwal, 2020).

Table 2 Empirical coefficients for Eqs. (34) and (37).

UO_2 (Eq. 34):									
A_1	0.3919	A_2	1.3100×10^{-19}	A_3	- 87.7	A_4	100.0	A_5	2.0391×10^{-25}
A_6	- 90.5	A_7	3.72264×10^{-35}	A_8	0.0	Q_3	2.6167×10^3		
$(U,Pu)O_2$ (Eq. 37):									
B_1	0.1007	B_2	7.57×10^{-20}	B_3	33.3	B_4	3.56	B_5	6.469×10^{-25}
B_6	0.0	B_7	10.3	Q_3	55.354×103	Q_4	70.451×10^3		

**Fig. 7** The steady-state creep rates of UO_2 at various temperatures with experimental data from [Burton and Reynolds \(1973\)](#).

The C/U ratio, porosity, grain size, and impurities can independently change the creep rate by several orders of magnitude. Stoichiometric and hypostoichiometric carbides ($C/U < 1.01$) are characterized by a higher creep rate than hyper-stoichiometric carbides due to UC_{2-x} precipitation ([Manara and Agarwal, 2020](#)). Finally, the stress exponent for single crystals is much higher ($n > 5$) than for polycrystalline UC ([Manara and Agarwal, 2020](#)).

For UN, values $A = 2.054 \times 10^{-3}$, $n = 4.5$, and $Q/R = 3.94 \times 10^4$ were reported in ([Hayes et al., 1990b](#)) with reference to Eq. (38). Also, the correlation in ([Hayes et al., 1990b](#)) is independent of grain size (i.e., $m = 0$) and is valid in the ranges $1770 \text{ K} \leq T \leq 2083 \text{ K}$ and $20 \text{ MPa} \leq \sigma \leq 34 \text{ MPa}$. Moreover, Eq. (38) with the aforementioned parameter values is valid for the creep of UN at 100% TD. Finally, the following porosity correction factor can be applied to the UN creep rate ([Hayes et al., 1990b](#))

$$f(p) = \frac{0.987}{(1-p)^{27.6}} \exp(-8.65p) \quad (39)$$

where p (vol. fraction) is the porosity.

Summary

In this article, an overview of the thermal and mechanical properties of the ceramic nuclear fuels UO_2 , MOX, UC and UN was given, with a focus on fresh fuel. In particular, the thermal conductivity, melting point, specific heat capacity, coefficient of thermal expansion, elastic constants, plasticity, fracture strength and creep rate were discussed. Examples of correlations from the literature for the evaluation of each property as a function of fuel state variables such as temperature, density and composition were given. Such correlations are used in fuel thermo-mechanics analysis. Furthermore, a collection of experimental data for fuel properties from various sources was included. It is worth noting that, for several properties, significant uncertainties are associated with the available experimental data and, consequently, with the correlations used in the fuel thermo-mechanics analysis. Uncertainties for specific properties were pointed out in the discussion. More details on ceramic nuclear fuel properties and the associated uncertainties can be found in the references provided.

Introduction

We start this high-level study of zirconium-alloyed metallic fuel by reviewing the work accomplished at the experimental breeder reactor (EBR-II) facility (Westfall, 2004; Walters, 1999; Koch, 2008; Sackett, 1997). EBR-II operated for approximately 30 years (1964–94) and achieved several important objectives related to metallic fuels. The first objective of EBR-II was to demonstrate that a closed fuel cycle was possible, meaning that the reactor would generate power while breeding fissionable plutonium from U-238. Additionally, the fuel would be reprocessed (separating fissionable material from fission products), re-fabricated (re-melted and cast into fuel slugs), and re-inserted into the reactor for additional power production. All of these processes were performed on-site, thus eliminating the need for transportation of radioactive materials off-site or requiring fresh fuel to be delivered. Due to the inability to remove all radioactive fission products and transuranics, the reprocessed fuel form was extremely radioactive. While this provided natural proliferation resistance due to handling difficulties, it also forced all reprocessing to be performed remotely. In 1969, ~35,000 fuel pins had been remotely recycled back into EBR-II.

Besides providing a working example of a closed nuclear fuel system, the collection of irradiated pins and associated post-irradiation examinations throughout the EBR-II irradiation testing mission provided an unmatched understanding of fuel behavior during irradiation. To set the stage for discussing material properties and the enlightening information that came out of EBR-II in the *Metallic Fuels Handbook* (MFH, 1988), a description of the fuel pin is required. A sketch of the fuel pin is presented in Fig. 1, which shows the solid cylindrical fuel encased within a cylindrical tube, referred to as cladding. The fuel is uranium-zirconium alloy (U-Zr) or uranium-plutonium-zirconium alloy (U-Pu-Zr). The cladding material is stainless steel; many were tested in the United States in EBR-II and HT9 was eventually selected in the 1990s as the preferred cladding alloy for that time.

There's a large gap between the fuel and cladding to accommodate the large swelling characteristic of metallic fuel. Liquid sodium, referred to as the sodium bond, is added into the fuel pin to fill the fuel/cladding gap and enhance heat conduction. The level of the liquid sodium is just above the top of the as-fabricated fuel column. The space inside the cladding, above the liquid sodium is called the plenum. The outside of the fuel pin is cooled by flowing liquid sodium.

This description of the basic metal fuel design provides context for this article, which describes the properties of metal fuel and how those properties contribute to fuel performance.

The aim for this article is to visually present the material models used by a fuel performance analyst using graphs to help the reader develop a basic and intuitive understanding of fuel behavior in a reactor. In simple terms, the fuel in a reactor heats up during operation, swells due to thermal expansion and the formation of fission gas, contacts the cladding, then releases the fission gas as the pores that contain the fission gas grow and interconnect forming a path to the fuel surface. The fission gas is (by design) contained inside the cladding, which isolates the fission gas and its damaging effects from the coolant and other reactor components. The material models required to describe and quantify these phenomena are thermal conductivity, heat capacity, thermal expansion, mechanical elasticity, creep, swelling, and constituent diffusion. Each of these properties is described in the following sections with graphs to show material property changes in response to changing temperature, composition, and porosity. Because it's important to view these material property models in relation to reality, material property measurements are shown along with the models. In this article, we present models and measurements for uranium-zirconium (U-Zr or binary) and uranium-plutonium-zirconium

Fig. 1 Simplified illustration of EBR-II metallic fuel pin (*not to scale*).

(U-Pu-Zr or ternary) fuel. Henceforth, the term metallic fuel refers to these fuel types. When a number is presented in reference to fuel alloy, such as U-10Zr, this means the fuel is 90 wt% U and 10 wt% Zr.

In this article, we provide an overview of the main properties of metallic fuels. In particular, thermal properties are dealt with in section **“Thermal properties,”** and mechanical properties are summarized in section **“Mechanical properties.”**

To make the work presented here clear, a brief description of porosity is required. As the fuel resides in a fission reactor, fissionable atoms react with neutrons to release energy, fission products, and additional neutrons. Fission products at fuel temperatures (~ 300 – 1500 kelvin (K) for illustration purposes in this article) can be solid, liquid, or gaseous, and the gaseous fission-product atoms (inert gases, in particular) will segregate and combine with other fission gases to form fission gas bubbles. These gas bubbles (porosity) form throughout the fuel. Herein, porosity is defined as the fraction of the small fission gas-filled volume over total fuel volume. The process of how materials react to irradiation is complicated, and the subject of ongoing research. For this introduction to metallic fuel properties, it's sufficient to understand that porosity forms, grows, and coalesces as fission occurs generating additional fission gases, and is an indication of how much fissioning has occurred.

Thermal properties

Thermal conductivity

The energy released via fission heats the fuel. The heat conduction equation describes well how this heat traverses through the fuel. An essential component of this equation is thermal conductivity, a material property that describes how much heat (thermal energy) can pass through a material in a given time. Its units are power per length-temperature. A model for thermal conductivity of U, U-Zr, and U-Pu-Zr alloys is provided in the *Metallic Fuels Handbook* (MFH, 1988), which was developed from many sets of measurements compiled in Kittel et al. (1977). Thus, the thermal conductivity is correlated as:

$$k_0 = A + BT + CT^2, \quad (1)$$

with

$$\begin{aligned} A &= 17.5 \left[\frac{(1 - 2.23W_{Zr})}{(1 + 1.61W_{Zr})} - 2.62W_{Pu} \right] \\ B &= 1.54 \times 10^{-2} \left[\frac{(1 + 0.061W_{Zr})}{(1 + 1.61W_z)} + 0.920W_{Pu} \right] \\ C &= 9.38 \times 10^{-6} (1 - 2.70W_{Pu}) \end{aligned} \quad (2)$$

where k_0 is the thermal conductivity of non-porous material (W/m/K), W_{Zr} is the zirconium weight fraction (wt/ W_{Pu}) is the plutonium weight fraction (wt/), and T is the temperature (K).

A correction for irradiation effects through the introduction and growth of porosity is calculated as follows: In case of closed porosity formed by isolated spherical pores, the Maxwell-Eucken formula can be used

$$k = k_0 \left(\frac{1 - p}{1 + \beta p} \right) \quad (3)$$

where k_0 is the thermal conductivity of non-porous material (W/m/K), p is the fractional porosity (–) (note that throughout this article (–) is used to denote a unitless quantity, such as porosity or strain), and β is the porosity constant that is typically taken as 2.5

for conservatism as recommended by Billone et al. (1968). The porosity p is calculated through additional material models for volumetric swelling due to fission gas production (see section “Swelling”).

Fig. 2 shows this model to demonstrate how fuel thermal conductivity changes as temperature is increased, for different fuel alloy compositions, and values of porosity. Fig. 2 shows that as the temperature within the fuel increases, the thermal conductivity increases. In other words, as the temperature increases, energy can flow more readily through the fuel. On the other hand, the fuel that includes plutonium (e.g., an alloy with uranium, plutonium, and zirconium; ternary fuel) has a lower value of thermal conductivity than fuel with only uranium and zirconium (binary fuel). This means that for the same energy generated within the fuel, a higher fuel temperature in ternary fuels is expected. Just as importantly, Fig. 2 shows that thermal conductivity decreases significantly for larger values of porosity, which is expected due to increased thermal resistance of pores. It's important to point out that temperature impacts all aspects of fuel performance, and emphasize that thermal conductivity directly influences fuel temperature. For context, measurements of thermal conductivity documented in Bauer and Holland (2017) are plotted along with the model in Fig. 2. These measurements were taken while the fuel was fissioning. The burnup (a measure of duration and intensity of fissioning) was 0.8 fissions per initial metal atom, or at.%, which is low.

Specific heat capacity

Specific heat capacity is defined as the amount of heat (or energy) required for a given mass to produce a unit change in its temperature. The units of heat capacity are energy per mass-temperature. Heat capacity is essential when describing how fast a material can change temperature when energy is deposited in or removed from the material. As such, it's especially important when energy is rapidly deposited in removed from the fuel (e.g., quick rises in power, or loss-of-flow events).

The correlation for specific heat capacity from Savage (1968) is split into the low temperature $\alpha + \delta$ region, and the high temperature γ region:

$$\begin{aligned} c_p^{\alpha+\delta}(T) &= 6.36 + 0.00636T, \quad \text{for } 25^\circ\text{C} < T < 600^\circ\text{C} \\ c_p^\gamma(T) &= 3.79 + 0.00623T, \quad \text{for } T > 650^\circ\text{C} \end{aligned} \quad (4)$$

where c_p is the specific heat capacity (cal/mol/°C) and T is temperature (°C).

A simple linear interpolation is employed in the $\beta + \gamma$ region:

$$c_p^{\beta+\gamma}(T) = \left(\frac{c_p^\gamma(T_{\text{high}}) - c_p^{\alpha+\delta}(T_{\text{low}})}{T_{\text{high}} - T_{\text{low}}} \right) (T - T_{\text{low}}) + c_p^{\alpha+\delta}(T_{\text{low}}), \quad (5)$$

Fig. 2 The thermal conductivity of zirconium-alloyed metallic fuel at varied compositions and porosity fractions (experimental data from Bauer and Holland (2017)). Note that binary fuel (U-Zr alloys) thermally is more conductive than ternary fuel (U-Pu-Zr) and pores within the fuel act to decrease thermal conductivity.

where T_{low} and T_{high} are the transition temperatures 600 °C and 650 °C, respectively. The designations $\alpha + \delta$, γ , and $\beta + \gamma$ denote material phase. Similar to the familiar solid/liquid/gas phases of matter, solid metallic alloys can go through material phase changes (i.e., transformations at the atomic level in the arrangement of the atoms which make up the alloy) in the presence of heat and fission. The result is significant changes to the material properties. Publications such as [Savage \(1968\)](#) have attempted to describe the effect of this phase change in material models for heat capacity, and that is reproduced here in [Fig. 3](#). It's important to note that all material properties are affected by phase change.

To limit the complexity of this article, and due to the fact that material property measurements during phase change are scarce, the effects of material phase are only shown for heat capacity. The measurements ([Savage, 1968](#)) used to develop this model are also presented in [Fig. 3](#).

Mechanical properties

Thermal expansion

The thermal response of the fuel affects the mechanical response via thermal expansion. Thermal expansion is simply uniform volume change due to heating or cooling. A relevant example is heating a bearing prior to placing it on a shaft in a mechanical system as part of the shrink fitting process. The bearing expands during heating, placed on the shaft, then shrinks during cooling, contacting the shaft to provide a strong mechanical bond. As the temperature in the fuel increases due to fission, the fuel expands in all directions. We show a few models for thermal expansion in [Fig. 4](#). The simplest model is a constant linear thermal expansion coefficient (α) multiplied by the difference between the current temperature and reference temperature ($\alpha\Delta T$). The reference temperature is where measurements begin. An average value of the fuel thermal expansion coefficient in the temperature range of 293 K (reference temperature) to 1200 K from [Saller et al. \(1956\)](#) is $\alpha = 1.88 \times 10^{-5} \text{K}^{-1}$. Additionally, models from [Touloukian et al. \(1975\)](#) and [Basak et al. \(2009\)](#) are shown in [Fig. 4](#) along with measurements from [Saller et al. \(1956\)](#). The change in trend between 923 K and 998 K, is due to a change in phase. Also note that thermal expansion is a volumetric phenomenon, but is usually expressed linearly, as in change in length divided by original length.

Elastic correlations

Elasticity, or modulus of elasticity, is the property of the fuel that quantifies how resistant it is to an applied load. The units are force per area. Due to the redistribution of zirconium in the fuel and the need to model both U-Zr and U-Pu-Zr fuel, correlations included in the elastic correlation for the fuel must be applicable to any concentration of plutonium or zirconium. Unfortunately, the

Fig. 3 The specific heat capacity of metallic fuel (*experimental data from Savage (1968)*). The fuel experiences a thermal gradient with high temperatures in the center and lower temperature on the surface that cause different material phases going from the center of the fuel to the surface. Three material phases are shown here; the $\alpha + \delta$ phase for the coolest section (*near the edge*), γ in the hottest section (*fuel center*), and $\beta + \gamma$ for the section in-between. See [MFH \(1988\)](#) for more information about material phases.

Fig. 4 The fuel thermal expansion for a constant thermal expansion coefficient and aforementioned models (Touloukian et al., 1975; Basak et al., 2009) (experimental data from Saller et al. (1956)).

available models for the elastic properties of U-Pu-Zr alloys are generally incomplete. Regardless, some correlations can be made given the sparse data, as described in MFH (1988).

The correlation for Young's modulus can be derived using data from U-11Pu-6.3Zr cast fuel pins as:

$$E = E_u(1 - \beta_E p) \left(\frac{1 + 0.17W_{Zr}}{1 + 1.34W_{Zr}} - W_{Pu} \right) \left(1 - 1.06 \left[\frac{T - 588}{T_{mu}} \right] \right) \quad (6)$$

where $E_u = 1.6 \times 10^5$ MPa is the Young's modulus for pure uranium at the reference temperature of 588 K, p is the fractional porosity (-), W_{Zr} is the zirconium weight fraction (wt/), W_{Pu} is the plutonium weight fraction (wt/), T is the temperature (K), and $T_{mu} = 1405$ K is the melting temperature of pure uranium. β_E is the Young's modulus degradation factor due to porosity and is typically 1.2.

The models in Fig. 5 display the value of elasticity as temperature increases for binary (U-10Zr) and ternary (U-19Pu-10Zr) fuels and the effect of porosity on binary fuel. The amount of zirconium and plutonium is shown in weight percent. Fig. 5 shows that the elastic modulus decreases as the temperature increases; in other words, the fuel becomes softer as the temperature gets higher. Furthermore, the presence of plutonium and/or increases in porosity result in softening the fuel. Measurements for pure uranium from Holden (1957) and ternary fuel from Harbur et al. (1970) are included in Fig. 5.

Another material property related to the modulus of elasticity is Poisson's ratio, which is a measure of a materials dimensional response to an applied load. Rather than a direct resistance to the applied load, like the elastic modulus, Poisson's ratio reflects how a material expands or contracts when a load is applied. As an example, when a tensile load is applied to a long circular bar in the direction of the bar's length, the diameter of the rod changes. Expressed formally, Poisson's ratio is the ratio of lateral strain to a longitudinal strain when subject to a longitudinal force.

The correlation for Poisson's ratio can be derived from the U-Zr correlation (MFH, 1988) as:

$$\nu = \nu_u(1 - \beta_p p) \left(\frac{1 + 3.4W_{Zr}}{1 + 1.9W_{Zr}} \right) \left(1 + 1.2 \left[\frac{T - 588}{T_{mu}} \right] \right) \quad (7)$$

where $\nu_u = 0.24$ is the Poisson's ratio of pure uranium at the reference temperature of 588 K, p is the fractional porosity (volume fraction, (-)), W_{Zr} is the zirconium (weight fraction, wt/), T is the temperature (K), and T_{mu} is the melting temperature of pure uranium (1405 K). β_p is the Poisson's ratio degradation factor due to porosity and is typically 0.8.

Fig. 6 shows Poisson's ratio as temperature increases for binary fuel (U-Zr) for two values of porosity. This graph indicates that as temperature increases, metallic fuel will strain more. Additionally, as porosity increases, the fuel strains more with the applied load. Not many measurements exist for this material property. As such, only the model is shown in Fig. 6.

Fig. 5 The elastic modulus at different alloy compositions, porosity fractions, and temperatures (*experimental data from Holden (1957) and Harbur et al. (1970)*). An observation from this plot is that binary fuel (U-Zr) is stiffer (more resistant to mechanical load) than ternary fuel (U-Pu-Zr). Also note that pores within the fuel act to decrease elastic modulus, i.e. soften the fuel.

Fig. 6 The Poisson's ratio of U-10Zr at varied porosity fractions.

Creep

In the simplest terms, elastic modulus, Poisson's ratio, and thermal expansion are used together to calculate the mechanical response or movement/deformation of the fuel. However, this is not sufficient to describe how fuel deforms while in the reactor. Another mechanism, called creep, must be included for a more representative description. Creep is defined as slowly evolving, irrecoverable strain due to applied load. Creep strain accelerates at high temperatures and due to stress induced by the presence of fission products.

A model for the combined thermal and irradiation creep of U-Pu-Zr is available with the creep rate modeled as a function of time, fuel porosity, effective stress, and fission rate (MFH, 1988) and is given as

$$\dot{\epsilon} = A_1(1 + 7.9p + 470p^2) \exp\left(\frac{-Q_1}{RT}\right) \sigma + A_2(1 - p^{0.67})^{-4.5} \exp\left(\frac{-Q_2}{RT}\right) \sigma^{4.5} + A_3 \dot{F} \sigma \quad (8)$$

where $\dot{\epsilon}$ is the creep rate (1/s), σ is the effective (Mises) stress (MPa), T is the temperature (K), p is the porosity fraction (—), $\dot{F}$ is the volumetric fission rate (fissions/cm²/s), Q_i are the activation energies (cal/mol), R is the universal gas constant (1.987/cal/mol/K), and A_{1-3} are empirical constants given as $A_1 = 5 \times 10^3$, $A_2 = 6$, and $A_3 = 7.7 \times 10^{-23}$.

The terms on the right-hand side of Eq. 8 respectively represent diffusional creep, power-law creep, and irradiation creep as it depends upon the fission rate. The activation energies for the thermal creep terms (Q_1 and Q_2) are given as $Q_1 = Q_2 = 52\,000$ cal/mol.

These U and Pu alloys have a phase change temperature of 923.15 K. Above this temperature, the creep rate equation changes to

$$\dot{\epsilon} = A_4(1 - p^{0.67})^{-3} \exp\left(\frac{-Q_3}{RT}\right) \sigma^3 + A_3 \dot{F} \sigma \quad (9)$$

where $A_4 = 8.0 \times 10^{-2}$ and $Q_3 = 28\,500$ cal/mol.

Fig. 7 shows a creep strain rate model from MFH (1988) that is a function of temperature and porosity at constant stress (load) of $\sigma = 9.8$ MPa. An essential point about creep is to note how it accelerates *nonlinearly* as the temperature increases and even more so as porosity increases (due to fission). This has a profound effect on the mechanical response of metallic fuel. Measurements from Saller et al. (1953) for binary fuel and from Argonne (Foote et al., 1965) for ternary fuel are also shown in Fig. 7, both in unirradiated conditions. Due to the nonlinear nature of creep, Fig. 7 uses a log scale on the y-axis, which clearly shows the significant differences between the models for different values of porosity.

Swelling

As the fuel is fissioning, fission gases and voids form within the fuel. The gas diffuses through the crystalline atomic structure and collects in the voids, referred to as pores or porosity. As the temperature increases and fission gases commence to form, these now filled voids grow and rapid fuel swelling occurs. The volume change in the fuel is similar to thermal expansion except the strain is driven by the increased pressure in the pores. The pores eventually coalesce into a smaller number of larger pores, and when the porosity reaches a value of about 20%, the gas-filled spaces form an interconnected path through the fuel to the sodium bond and plenum. Further swelling in the fuel decreases significantly because the gas escapes the fuel.

Fig. 7 The steady-state creep rates as a function of temperature and porosity (experimental data from Saller et al. (1953) and Foote et al. (1965)).

The derivation for the mechanistic fuel swelling model for U-Pu-Zr systems used here was originally presented in Olander (1976). The model is based on the mechanical force balance for an equilibrium fission gas bubble (note that bubble and pore are used interchangeably here) and the equation of state:

$$P = \frac{2\gamma}{r_b} - \sigma_h + \sigma_{cr} \quad (10)$$

where P is the pressure of the fission gas in a bubble (Pa), γ is the surface tension of the fuel (N/m), r_b is the fission gas bubble size (m), σ_h is the hydrostatic stress in the fuel (Pa), and σ_{cr} is the creep strength stress of the fuel (Pa). Assuming that the gas in the bubble is governed by the ideal gas law and rearranging to solve for the volume of the bubble leads to an expression for the volumetric strain due to swelling:

$$\left(\frac{\Delta V}{V_0}\right)_g = \left(\frac{3}{4\pi}\right)^{1/2} \frac{[(kT/2\gamma)Y_{Xe}\dot{F}t]^{3/2}}{N^{1/2}} \quad (11)$$

where k is the Boltzmann constant (1.38×10^{-23} m²/kg/s²/K), T is the temperature (K), Y_{Xe} is the gaseous fission product yield (atoms/fission), $\dot{F}$ is the fission rate density, (fissions/m³/s), t is time (seconds), N is the number density of bubbles (number of bubbles), V is the current volume (m³), and V_0 is the original volume (m³).

Once the gaseous fuel swelling is calculated, it is used to calculate the porosity:

$$p = \frac{\left(\frac{\Delta V}{V_0}\right)_g}{1 + \left(\frac{\Delta V}{V_0}\right)_g} \quad (12)$$

Models that describe the swelling and formation of porosity are shown in Fig. 8 from Olander (1976). The plots show nonlinear porosity formation and swelling as temperature increases for two fission rates. Porosity formation and swelling almost overlap, but there are slight differences. Measurements of fission gas-induced swelling for these binary and ternary fuels as a function of burnup and temperature aren't available, so measurements are not included in Fig. 8. Swelling measurements for other uranium alloy materials can be found in McDonnell and Sturcken (1975).

Constituent redistribution

Another phenomenon that is important to understanding fuel behavior is the composition of the fuel. As the fuel fissions and heats up, the uranium and zirconium migrate from a uniform distribution to a distribution with a higher concentration of zirconium and

Fig. 8 Fuel swelling as a function of temperature and fission rate.

a correspondingly lower concentration of uranium in the fuel center via a process called diffusion. This is important because the concentration of the alloy constituents influences other material properties and will affect the spatial intensity of fissions as the uranium concentration changes. The material property that governs this process is called the diffusion coefficient. It is analogous to thermal conductivity. The units are in length squared per time. The Metallic Fuels Handbook shows measurements of diffusion coefficients for uranium and zirconium in binary (U-Zr) fuel from [Adda et al. \(1957\)](#) and [Müller \(1959\)](#) at various temperatures. These measurements are shown in [Fig. 9](#). For more detail in how these diffusion coefficients are modeled, see [Galloway et al. \(2015\)](#).

Summary

From observations of [Figs. 2–8](#), one can understand how the fuel properties and characteristics change as temperature and fission increase. The energy released by fission heats the fuel, and the fuel's thermal conductivity and heat capacity define how heat conducts through the fuel. As the temperature of the fuel increases, it expands based on thermal expansion, elastic modulus, Poisson's ratio, creep, and fission-gas-driven swelling. Porosity generated by fission eventually interconnects, and fission gas is released from the fuel, which reduces the driving force for swelling and thereby slows swelling. Although more detail is necessary for thoroughly describing how the fuel behaves, especially during transients, early in fuel life, and after long exposure to irradiation, the compilation of the property models described here provides insight on how changes in the metallic fuel material lead to phenomena that impact cladding integrity and performance. A useful review of binary (U-Zr) and ternary (U-Pu-Zr) properties can be found in [Janney and Hayes \(2018\)](#) and [Janney et al. \(2019\)](#), respectively.

The fuel's cladding is a vital component of the metallic fuel system. Cladding is the structural barrier that retains fission products and is the thermal medium to the sodium coolant. The fuel properties discussed here significantly affect the cladding; this relationship cannot be over-emphasized. Due to the large fuel swelling and concerns about the fuel contacting and stretching the cladding, many experiments were conducted during EBR-II to determine the fuel rod features necessary such that fission-gas-driven swelling would essentially stop before contacting the cladding. It was determined that the ratio of fuel cross-sectional area to total cross-sectional area available within the cladding should be 75%. This so-called smear density of a fuel rod is illustrated in [Fig. 10](#), which shows a schematic of a fuel rod cross section. This ratio was determined such that by the time the fuel swelling slows down (due to porosity interconnection and fission gas release), the fuel softly contacts the cladding. The force applied to the cladding by the fuel depends very much on all the material properties presented in this article. While there are other features beyond the scope of this article that are also important to the structural integrity of the cladding, such as fuel cladding chemical interaction, the properties and description presented here make the connection and emphasize the relationship between fuel properties, cladding mechanical response, and containment of fission products and, specifically, fission gas within the cladding—a critical design feature.

The information presented here introduces how zirconium-alloyed metallic fuel responds to elevated temperature and fission. Furthermore, it forms the basis for progressive understanding as more detailed sources are explored.

Introduction

Molten salt reactors (MSRs) are a nuclear reactor concept that use molten salts as fuel and coolant. MSRs were first studied in the U.S. shortly after World War II with intended application for aircraft propulsion and civilian power production. These efforts began at Oak Ridge National Laboratory (ORNL) with the Aircraft Nuclear Propulsion Program in 1949. The nuclear propulsion programs

were terminated in 1961 and interests in MSRs for civilian power production continued into the early 1970s. Worldwide, only two MSRs have operated: the Aircraft Reactor Experiment (2.5 MWt) from November 3–12, 1954, intended to lead to a design for aircraft propulsion; and the Molten Salt Reactor Experiment (MSRE) (8 MWt) between June 1, 1965 and December 12, 1969, which demonstrated technologies intended for civilian power production. A detailed review and overview of these ORNL experiments can be found in literature (Fredrickson et al., 2018).

A common feature of MSRs for steam generation of electrical power is the use of molten salts as heat transfer media within two separate molten salt loops: primary and secondary. The primary salt loop extracts heat from the reactor's core, and the secondary salt loop extracts heat from the primary salt loop. Steam is produced when a water loop extracts heat from the secondary salt loop. Several different designs of MSRs have been proposed and are most easily differentiated by the type of fuel. The designs for which fissile inventory is dissolved in molten salt are referred to as salt-fueled MSRs. For example, enriched uranium is added directly to the salt as uranium fluoride or uranium chloride. As the salt flows through the reactor's core, the heat of fission is generated within the salt itself. The designs for which the fissile inventory is kept separate from the salt are referred to as molten salt-cooled reactors. For example, enriched uranium fuel is contained in cladding and stationary within the reactor's core. As the salt flows through the reactor's core the heat of fission is generated within the uranium fuel and transferred to the salt coolant.

More complex MSR designs include breeder reactors that use a $^{232}\text{Th}/^{233}\text{U}$ fuel cycle (Fredrickson et al., 2018; Heuer et al., 2014) and are capable of producing excess fuel materials, and burner reactors whose function is to consume nuclear materials recovered from spent nuclear fuels or nuclear material produced for nuclear weapons (Gat et al., 1991). MSRs have several promising, yet unrealized features that make them attractive for nuclear reactor applications. These include high coolant temperatures, low pressure cooling systems, enhanced intrinsic safety features, and greater thermal-to-mechanical efficiencies than, for example, Light Water Reactors (LWRs). Fluoride, and to a lesser extent chloride, salt systems have received the most attention (Gen IV Forum, 2018; Serp et al., 2014). Table 1 lists a variety of fuel and coolant salt systems historically proposed for different MSR applications.

Nuclear material safeguards and monitoring are important considerations as are long-term waste treatment and disposal (Bauman et al., 1977). Radioactive wastes from MSRs will require treatment and disposal technologies that are different than those developed for LWR fuel waste management. There are several technical requirements placed on molten salt fuels and coolants. The physical-chemical properties are important to basic engineering design aspects, including heat capacity, thermal conductivity, viscosity, vapor pressure, density, and radiation performance.

Many of the technical challenges of MSR design are related to the chemical and electrochemical properties of the molten salts, particularly regarding the chemical compatibilities of the molten salts with the materials of construction of the reactor components. In the case of salt-fueled MSRs, fission events generate fission products that bond with the halides to form new and complex salt species. Corrosion in MSRs is strongly affected by the molten salt chemistry and purity of reagents; therefore, salt purification is an important aspect of consideration for reactor applications. The next section discusses the molten salt properties important for their selection as candidate fuel or coolant salts for reactor applications including isotopes, neutronics, thermophysical properties, and materials corrosion. The purification methods for both fluoride and chloride salts are also reviewed in the later sections.

Properties of molten salts for reactor designs

Though most literature considers fluoride and chloride salt systems for MSR applications, there are no specific reasons deterring the use of iodine and bromine other than the lack of experience and knowledge (Holcomb et al., 2011). In fact, heavier halides can improve burning and breeding by providing a harder neutron spectrum, which can be advantageous for fast reactor applications. Since the purpose of this article is to review the existing knowledge base on MSRs, we leave the consideration of the heavier halides as a front-line research endeavor and limit the exposition to chloride and fluoride systems. Chloride and fluoride systems have distinctive characteristics that are relevant to MSR applications. Understanding these characteristics is important to comprehending the rationale and consequence of selecting one system over the other for specific applications.

Table 1 Summary of historic and proposed salt systems and compositions for MSR applications (World Nuclear Association, n.d.; Fredrickson et al., 2018).

Salt composition	Use in reactor	MSR application	Years
NaF-ZrF ₄ -UF ₄ (53.09-40.73-6.18) mol%	Fuel Salt	Aircraft Reactor Experiment 2.5 MWt	1954
LiF-BeF ₂ -UF ₄ (68.5-31.3-0.2) mol%	Fuel Salt	Two-fluid MSBR, 1000 MWe	1961–1970
LiF-BeF ₂ -ThF ₄ (71-27-2) mol%	Blanket Salt		Design only
LiF-BeF ₂ -ThF ₄ -ZrF ₄ (68-29.2-0.8-5) mol%	Fuel Salt	MSRE, 8 MWt	1965–1969
LiF-BeF ₂ -ThF ₄ -UF ₄ (68-22-9-1) mol%	Fuel Salt	Molten Salt Converter Reactor, 1000 MWe	1961–1965
LiF-BeF ₂ -ThF ₄ (68-23-9) mol%			Design only
LiF-BeF ₂ -ThF ₄ -UF ₄ (71.5-16-12-0.5) mol%	Fuel Salt	Molten Salt Breeder Experiment, 150 MWt	1969–1970
KNO ₃ -NaNO ₂ -NaNO ₃ (44-49-7) mol%	Coolant Salt		Design only

Isotopes

Fluorine is the lightest halide with the average atomic mass of 18.998 g/mol. Chemically, it is the simplest among the halides since it has only one oxidation state available (-1). It is also the simplest isotopic composition because ^{19}F is the only stable isotope among its 17 known isotopes. All the other fluorine isotopes have relatively short half-lives and are not found naturally. The simple chemistry and absence of long-lived isotopes favor fluorine as the top halide candidate for the MSR application. Chlorine is the second lightest halide with the average atomic mass of 35.45 g/mol. Chemically, it is more complex than fluorine because five oxidation states (-1 , 1 , 3 , 5 , and 7) are possible, though it usually exhibits a -1 oxidation state. It has 25 known isotopes and two of them are stable in nature, ^{35}Cl (76% natural abundance) and ^{37}Cl (24% natural abundance). All the other isotopes have relatively short half-lives except ^{36}Cl (301,000-year half-life). The long half-life of ^{36}Cl can be a concern for long-term nuclear waste management.

Neutronics

Lithium fluoride is a commonly adopted constituent for salt-fueled MSRs based on the fluoride system (e.g., FLiBe). Lithium has two stable isotopes, ^6Li (7.59% natural abundance) and ^7Li (92.41% natural abundance). A problem of adopting lithium fluoride to an MSR system is the production of tritium from the fission of ^6Li . Tritium emits beta radiation with a half-life of 12.32 years, which is sufficiently long to require that it be carefully managed to prevent release to the environment. Thus, most proposed molten salt reactor concepts call for salts enriched in ^7Li to minimize tritium production from ^6Li . Literature reports various means to separate lithium isotopes (Hoshino and Terai, 2011; Arisawa et al., 1982; Symons, 1985; Black et al., 2009).

Stable and naturally abundant ^{35}Cl can capture a neutron and become ^{36}Cl . ^{36}Cl is a long-lived isotope and long-term reactor operation with abundant ^{35}Cl can accumulate ^{36}Cl . ^{36}Cl is a high-energy beta emitter and is soluble in water as the salt making it very mobile in the natural environment. Thus, the disposition of the used salt can be problematic for a long-term repository. As discussed earlier, chlorine has two stable isotopes, ^{35}Cl (76% abundance) and ^{37}Cl (24% abundance). Separation of ^{35}Cl and ^{37}Cl can be achieved by various methods such as liquid-phase thermal-diffusion-based separation (Kranz and Watson, 1953) and gas centrifuge (Ragheb, 2012). By minimizing the partition of ^{35}Cl to the reactor, ^{36}Cl production can be minimized. Another source of ^{36}Cl is the $^{39}\text{K}(n,\alpha)^{36}\text{Cl}$ reaction. Thus, adopting KCl is not advisable for the MSR application. Even with this shortfall, the chloride salt system has received attention primarily for fast reactor applications including TerraPower's Molten Chloride Fast Reactor (Kramer, 2019). Chloride salts are advantageous in fast reactors because they have higher solubilities for actinides and are harder to neutrons (less neutron moderating) compared to the fluoride salts.

Thermophysical properties

Fundamental thermophysical properties, such as melting temperatures, specific heat capacity, density, viscosity, thermal conductivity, and thermal diffusivity are critical salt characteristics that impact the design of MSRs, for both fuel and coolant salts (Samuel, 2009; Capelli, 2015; Beneš and Konings, 2012; Fredrickson et al., 2018; Korin and Soifer, 1997). The composition and chemical properties of the fuel and coolant salts vary with time primarily due to fuel burnup (i.e., the fission process that converts fissile isotopes to fission products) and materials corrosion. This leads to changes in actinide, fission product, and corrosion product concentrations within the salts. Consequently, relating the changes in salt composition to changes in the thermophysical properties is important to ensure safe and efficient reactor operations. Because small changes in composition can lead to significant changes in the associated thermophysical properties of the salt, rigorous methods must be developed to prepare high-purity samples used for measuring salt properties, and rigorous analytical practices are needed to make reproducible measurements.

A useful analogy for the physical behavior of molten salts is to compare the properties of molten salts to those of liquid water at room temperature. Most alkali or alkaline earth halides above their melting points have viscosities, heat transfer characteristics, and optical properties similar to those of liquid water, with the obvious difference of temperature. However, just as with aqueous chemistry, changes in the chemical composition of a molten salt solutions can cause large changes in thermophysical properties. Due to the complexity of the composition fluctuations as a function of operating time, the amount of experimental data needed to optimize a molten salt mixture for a particular application is extremely large. Many of these properties are sensitive to impurities, including dissolved metals, moisture, and oxygen-containing impurities, such as oxides, hydroxides, sulfates, carbonates, and oxyhalides. The wide array of salt compositions being investigated increases complexity, as fuel and coolant salts vary by design and neutronic needs for specific MSR concepts. Some of the most important properties needed for fuel or coolant salt selection, reactor design, and computational modeling are listed in Table 2 (Diamond et al., 2018; Magnusson et al., 2020; Williams and Britt, 2017). Although Table 2 is not an all-inclusive list of properties and measurement techniques, it provides an overview of techniques available to determine the properties most important to molten salt performance. The importance of these properties is described in greater detail in the sub-sections below.

It is important to note that salt compositions must be selected not only for neutronic characteristics, but also for properties that ensure robust reactor operation. Computational models validated with limited and select experimentally measured properties data enable the prediction of thermophysical properties over a much broader range of temperature and chemical compositions than realistically can be measured experimentally. High temperature measurements for accurate and reproducible thermophysical properties of molten salts are difficult due to the unique experimental conditions required.

Table 2 Thermophysical and thermochemical properties needed for MSR applications and some experimental techniques for determining each property.

There are currently no benchmarks or data collection standards for molten salt samples, and very few commercial instruments are designed to work with molten salts in an off-the-shelf configuration. Salts must be synthesized, purified, and blended to composition with care because of their highly hygroscopic and corrosive nature, and materials compatibility must be at the forefront when determining the experimental design and atmospheric control of instruments.

Phase diagrams

Phase diagrams that describe the solubility limits and melting temperatures of salts as a function of composition are important tools for MSR design. To allow the reactor the widest operating temperature range possible, it is desirable to select a salt system with the lowest melting point possible, while simultaneously maintaining high temperature stability and optimizing other properties. This is typically accomplished by selecting a eutectic composition of two or three higher-melting-point salts; however, in some instances, it is desirable to deviate from eutectic composition for one or more reasons. The commonly used FLiBe composition, 2LiF:BeF₂, is one such example where the composition is chosen to optimize both the melting point and the viscosity. The phase diagram of the binary LiF-BeF₂ system is shown in Fig. 1 (Beneš and Konings, 2009). Addition of more BeF₂, up to the 52 mol% BeF₂ eutectic point, lowers the melting point further; however, due to the complex intramolecular interactions in FLiBe, the viscosity of the eutectic composition is much higher than at the peritectic 2LiF:BeF₂ composition (i.e., 66 mol% LiF, 34 mol% BeF₂; Beneš and Konings, 2009). Additions of other components to the base binary salt composition, such as actinides, fission products, corrosion products, and impurities also affect the phase relations. Consequently, it is necessary to know how the additions of these various species affect the liquidus temperature and solubility limits of other species.

Density and thermal expansion

For salt-fueled MSRs, the inverse relationship between density and temperature is one of the primary passive safety features, as any sudden increase in salt temperature will quickly cause a decrease in fuel density. As the fuel density directly affects the reactivity of the core, an increase in temperature has a net impact of lowering the reactivity coefficient ($k_{\text{effective}}$) and thus the power generation rate. This negative reactivity feedback mechanism is one of the most attractive features of salt-fueled MSRs, but to realize this feature, it is necessary to accurately understand how density fluctuates with temperature and composition. Densities for molten salts are typically between 1.62 g/cc for molten LiCl-KCl eutectic at 500 °C (Sridharan, 2012) to 3.1 g/cc for the NaCl-UCl₃ eutectic at 600 °C (Desyatnik et al., 1975).

Fig. 1 LiF-BeF₂ binary system phase diagram (Image reproduced from Beneš and Konings, 2009).

Specific heat capacity

The primary purpose of an electrical power producing reactor is to generate heat. Because the properties of a reactor's structural materials are temperature dependent, one of the key safety functions of a reactor is to transfer heat effectively from the core to the heat removal system. The specific heat capacity of a substance is a measure of the amount of thermal energy required to elicit a temperature change. Typically this is measured in terms of J/(kg K), with typical values for molten salts being between approximately 1200 and 2100 J/(kg K) (Sohal et al., 2013). When compared to the specific heat of water of 4185 J/(kg K) (at 20 °C), salts have approximately half the specific heat capacity. However, given the higher density of salts, the volumetric heat capacity of most molten salts is comparable to that of water, meaning that molten salts are very effective heat transfer fluids.

Viscosity and rheology

When considered together, rheology and viscosity provide an understanding of how liquids flow in an unconstrained system and how they behave under the influence of an applied force. An accurate understanding of these parameters is critical for describing the flow of molten salt through the system, including through pumps, piping, and in-core components. Molten salts are Newtonian fluids that follow an Arrhenius-type equation describing their exponential decrease in viscosity with reciprocal temperature (Wakeham et al., 1991; Ingersoll et al., 2007). Due to this behavior, viscosity varies more with temperature than other thermophysical properties. As mentioned above, viscosity is also impacted by variations in composition. For salts containing cations with typical oxidation states greater than 1, such as BeF₂, increasing concentration of the cation can cause an increase in viscosity (due to edge- and corner-sharing interactions between adjacent halide anion coordination shells, which are the loosely organized atomic species that exist in a liquid phase). This behavior has also been observed in melts containing MgCl₂ (Wu et al., 2020) and UCl₃ as well (Okamoto and Ogawa, 1999; Okamoto et al., 2005). Consequently, the effect of the buildup of fission products in salt-fueled MSRs on viscosity is important to understand, as most salt-soluble fission products have an oxidation state greater than 1.

Wetting and surface tension

Wetting properties, such as surface tension and contact angle, influence interfacial behavior (foaming, intrusion into pores, and wetting of surfaces). Determination of interfacial behavior enables the estimation of mechanistic details pertaining to the corrosion of structural materials by molten salts. Under the influence of the forces acting on molecules in the bulk liquid and at the surface, the liquid contracts its surface area to maintain the lowest surface free energy, as shown in Fig. 2 (top image). If the interfacial energy of the liquid-solid interface (i.e., the free energy of the interface) is less than the free energy of the bulk liquid, then the liquid will more easily wet the solid surface; a wetted condition allows more chemical interaction between the liquid molecules and the surface, such as corrosion. The term free energy describes the propensity of a chemical system to spontaneously change. Generally, chemical reactions tending toward equilibrium occur in ways that minimize free energy. Measuring the angle at which the drop contacts the surface provides an understanding of the forces at play within the fluid and in relation to the material. Contact angle measurements performed at ORNL during MSRE operations demonstrated that the contact angle fluctuated with the redox chemistry of the salt and the presence of moisture (Briggs, 1964b; Rosenthal et al., 1969; Ziesing, 1953; Yuan and Lee, 2013). (*Redox chemistry or redox potential*: The term is defined as the tendency of a chemical species to acquire electrons and become reduced. It is a measurable voltage that is related to the concentration of the reduced and oxidized species in the molten salt solution.)

Molten salt purification

The need for the purification of commercial salts was identified early on during MSRE operation at ORNL (Kelleher et al., 2015). Among the impurities present in salts, moisture and oxides are the main species of concern due to their prevalence and their effects on salt chemistry and corrosion. Other, minor impurities include alkaline earth and transition metal fluorides and chlorides. Most salts are highly hygroscopic, with some having such an extreme affinity for water that they tend to deliquesce in presence of humidity, necessitating their handling and experimentation under inert and dry atmospheres (gloveboxes, hotcells, etc.). Absorbed water in salts cannot always be removed by simple heating and drying (Kelleher et al., 2015), as the hydrated salts undergo hydrolysis upon transition to the liquid phase if the moisture is not removed prior to melting, leading to the formation of hydroxides and/or oxides through the Reactions (1) and (2) (X represents F or Cl):

Fig. 2 (Top) Schematic of a sessile drop and the balance of surface tensions at the three-phase contact line. (Below) Contact angle of FLiBe and FLiNaK on two different grades of nuclear graphite—IG110 and Matrix A3. A metallic cube (1 cm side) is included in the picture for scale reference. Both FLiBe and FLiNaK exhibit low wetting on graphite surface. (Below) Image reproduced from Delmore AR, Derdeyn W, Gakhbar R, Scarlat RO (2018) Wetting of graphite by molten fluoride salts: initial experiments. In: Transactions of the American Nuclear Society, Vol. 118, Philadelphia, Pennsylvania, June 17–21, 2018.

The hydroxide ions thus produced results in precipitation of metal ions, attack ceramics, metals, or other container materials, and are more easily reduced compared to other components of the salt; leading to severe corrosion of the container materials. The difficulty of removing the last traces of residual moisture from the salts has often necessitated rather arduous drying procedures. Several techniques have been considered and applied for molten salt drying and purification, including the removal of cationic and anionic impurities, and are summarized in [Table 3](#).

Table 3 Various purification methods considered for fluoride and chloride salt systems.

<i>Techniques</i>	<i>Application/Details</i>	<i>References</i>
Vacuum Drying	Typically used to drive off the majority of moisture present in commercial salts	Kurley et al. (2019)
Distillation, Vacuum Distillation	Common purification technique for separation of impurities from salt	Young and Mamantov (1990)
Gas Sparging	<i>Sparging with an inert gas:</i> Removes volatile components including HCl, H₂S, sulfur and hydrocarbons <i>Cl₂ or HCl for chloride salts:</i> • A common purification technique for removal of hydroxide impurities • Cl₂ has the advantage of being much easier to dry than HCl; however, both gasses at elevated temperatures are highly corrosive <i>Carbochlorination:</i> The oxide impurity in some chloride salts (e.g., MgCl₂) is more difficult to remove by HCl sparging. In such cases, a chlorocarbon compound, such as phosgene or CCl₄, can be used in conjunction with chlorination <i>Mixture of HF/H₂ gas for fluoride salts:</i> • In addition to removing moisture and oxide impurities, this method also removes anionic contaminants, such as chloride and sulfur • Contaminants not removed by the H₂/HF treatment include corrosion products from the materials of construction and neutron activation products <i>NF₃ gas as an alternative to HF:</i> • Removes oxide and water contaminants; to convert contaminant graphite and corrosion products to soluble or volatile fluorides • NF₃ is significantly less toxic compared to HF • Significant global warming potential impact	Johnson et al. (1969) Maricle and Hume (1960) Sun et al. (1991) and Kurley et al. (2019) Kelleher et al. (2015) Scheele et al. (2017)
Dry Chemical Treatment	As an alternative to HF gas, solid NH ₄ HF ₂ was used for conversion of U and Th oxides to tetrafluorides and for subsequent removal of oxygen-containing impurities from fluoride salt constituents	Ignatiev and Surenkov (2017) and Ignatiev et al. (2014)
Zone Refining	• Zone refining is a recrystallization technique for the preparation of ultra-pure materials, commercially • A major advantage of this process is the elimination of the need to separate pure from impure fractions, as in fractional crystallization • Process time can be reduced by having the zones closer, and throughput can be improved with a setup with multiple heaters. • Impurities with distribution coefficient equal to or higher than 1 (Fe, Ni, Ca, Co) are difficult to remove by zone refining, necessitating additional purification steps	Ghosh et al. (2009) , Pamplin (2013) , and Shim et al. (2017)
Reduction by Active Metals or Alloys	Involves the reduction of the salt with a constituent active metal such as an alkali metal, beryllium, or zirconium. An example is the use of a Mg-Cd alloy for removal of metallic impurities from MgCl ₂ . Oxides, hydroxides, and water react with Mg to form hydrogen and insoluble MgO	Johnson et al. (1969)
Multi-step Purification	Due to differences in the separation characteristics of various ionic impurities, utilization of multiple purification procedures in series may be warranted An example is the multi-step procedure purification of chloride salt (LiCl) following various steps:	Hinks and Susman (1974)
	a. Solvent extraction: to chemically remove ions that cannot be removed by zone refining b. Vacuum dehydration: to remove bulk moisture c. Halogen treatment: to remove residual hydroxide species d. Zone refining: for removal of cationic impurities	

Corrosion in molten salts and redox control

Corrosion in molten salt

Molten salts are corrosive to MSR structural materials at high temperatures, particularly through a reactor's service life of 30 years or more. Therefore, successful design and operation of an MSR requires a thorough understanding of corrosion behavior of materials in molten salts. In contrast to traditional high temperature oxidizing environments, the formation of a passivating oxide layer on the surface of alloys is typically prevented due to the solubility of the corrosion products in the molten salt (Sridharan and Allen, 2013; Zhang et al., 2018). As a result, the corrosion resistance of alloys for MSR applications largely depends on the thermodynamic inertness of the alloy in molten salts.

The MSRE generated a large amount of data and experience associated with salt chemistry and materials corrosion in molten fluoride systems. More recently, chloride salts have been considered as top candidate fuel salts for some fast spectrum MSRs, but currently corrosion data is less available. Molten fluoride and chloride salts both share some features of salt chemistry and corrosion behavior in MSR environments, meaning that experience with fluoride salts can inform the analysis of data for chloride salts. However, the thermodynamic property differences between fluoride and chloride salts leads to some differences in corrosion performance of materials and salt chemistry control. Several comprehensive review papers on salt chemistry and materials corrosion in these salts are available (Guo et al., 2018; Wang et al., 2018; Ignatiev and Surenkov, 2017; Zhang et al., 2018). Generally, there are several different corrosion mechanisms (Williams and Britt, 2017; Sohal et al., 2013): (1) intrinsic corrosion, (2) impurity driven corrosion, (3) temperature gradient-driven corrosion, (4) dissimilar metal-driven corrosion, and (5) stress corrosion cracking.

Intrinsic corrosion

Intrinsic corrosion is caused by chemical reactions of the material constituents with the salt itself. When the salt is perfectly clean and pure and the metal surface is free from any oxide layers, the corrosion is a result of redox reactions between the alloying elements in the metal and the ions in the salt. Because alkali and alkaline earth halide salts are very chemically stable, the reaction between these salts and the alloying elements in stainless steels and nickel-based alloys (e.g., Cr, Ni, Mo, W etc.) are thermodynamically unfavorable, meaning that intrinsic corrosion rates should be minimal.

Impurity driven corrosion

Impurities including moisture, oxides, and other oxidants in molten salts can come from different sources during manufacturing, handling, storage, and operations. The impurities can react with the salt melt, form corrosive agents, and then attack the structural materials. Reactions (3) through (6) (where X represents F or Cl) show the typical impurity induced corrosion reactions.

Chromium is used here as an example as it is the most active alloying element in most structural alloys, meaning that it will be preferentially depleted from the alloy before other alloying elements are attacked. Similar reactions can occur with other alloying elements depending on the thermodynamic equilibrium of the salt-metal interface. It is important to note that impurity driven corrosion causes accelerated corrosion initially, and as impurities are consumed, the corrosion rate will decrease assuming no further impurities are added (Sridharan and Allen, 2013).

Temperature gradient-driven corrosion

The equilibrium constant for the reaction between salt and the main active alloying element, typically chromium, is temperature dependent. Considering uranium fluoride salts as an example, at higher temperatures, the equilibrium constant for Reaction (7) is higher, which means higher corrosion rates, while at lower temperatures, the equilibrium constant is lower, and the corrosion rate is lower.

In a system with large temperature gradients, such as in an operating MSR or thermal convection loop (*Thermal convection or natural circulation loop*: Natural convection flow results from the difference in density of the fluid (molten salt in this case) in the hot and cold portions of the loop. Thus, the flow is generated and maintained without the use of any external source like pumps, fans, suction devices, etc.), this temperature dependence for the equilibrium concentration of CrF_2 in the salt drives mass transport of CrF_2 from the hot sections to the cold regions. At the colder areas, when the concentration of CrF_2 from the hot sections is greater than the equilibrium concentration of CrF_2 in Reaction (7), the equilibrium can shift to the left side and lead to the deposition of chromium. Fig. 3 represents an example of the corrosion difference in hotter and colder sections of a schematic thermal convection loop with test samples inserted: more severe corrosion in hotter sections and chromium deposition in colder sections (Koger, 1972). This temperature gradient-driven corrosion is considered the primary corrosion mechanism for sustained corrosion in MSRs.

Fig. 3 Micrographs of Hastelloy N exposed to $70\text{LiF}\cdot 23\text{BeF}_2\cdot 5\text{ZrF}_4\cdot 1\text{ThF}_4\cdot 1\text{UF}_4$ molten salt in a thermal convection loop after 9.2 years. Image reproduced from Koger JW (1972) "Evaluation of Hastelloy N Alloys after nine years exposure to both a molten fluoride salt and air at temperatures from 700 to 560°C". Oak Ridge National Lab Report, ORNL-TM-4189.

Dissimilar materials effects

When dissimilar materials are present in the molten salt, the corrosion rate can be accelerated. The dissimilar materials do not necessarily have to be electrically contacted with each other, particularly when one of the materials has a chemical affinity for the corroded species in the salt and forms a compound, as is the case for carbide-forming alloying elements in the presence of graphite, such as chromium (Sridharan and Allen, 2013). When the two dissimilar materials are in electrical contact, galvanic corrosion occurs, leading to accelerated corrosion of the more active material. For example, Alloy 800H tested in a graphite crucible was found to have a much higher corrosion rate than when tested in an Alloy 800H crucible (Sridharan and Allen, 2013). It should be noted that a similar galvanic corrosion effect can occur on the micro-scale in alloys due to microstructural dissimilarities between different regions of the material, such as precipitates and grain boundaries and the composition differences between welds and the base material (Sohal et al., 2013).

Stress corrosion cracking

In the MSRE, it was found that tellurium-assisted stress corrosion cracking occurred in Hastelloy N in FLiBe. Tellurium was found to diffuse into the Hastelloy N and form brittle intergranular precipitates. A concerted effort to control this effect led to the discovery that tellurium-assisted stress corrosion cracking can be avoided by maintaining the salt under more reducing conditions by using

a lower ratio for UF_4/UF_3 (for example 95:5 or lower) and by using a modified Hastelloy N alloy with additions of Ti or Nb to preferentially react with Te (McCoy, 1978).

Redox control

Transmutation and fission reactions in the reactor deplete fissile materials and lead to accumulation of fission products in fuel salt, changing the composition and redox state of the salt to generate a net-oxidizing environment. It is necessary to control the redox properties of the salt to minimize the corrosion of materials. There are various strategies for redox control of salt, depending on the thermodynamic properties of the halide salts, including H_2/HF sparging, active metal insertion, active electrochemical means, and the strategic use of salt components with multiple possible valence states to buffer the redox state of salt (Zhang et al., 2018).

During operation of the MSRE, the redox control of fuel salt was achieved by maintaining a UF_4/UF_3 ratio of about 100:1, leading to a redox state that is not unacceptably corrosive to the non-ferritic materials of construction (i.e., nickel-based alloys). It should be noted that the reason for maintaining such a high UF_4/UF_3 ratio is that in molten fluoride salts UF_3 is not stable unless a large excess of UF_4 is present due to a disproportionation reaction shown in Reaction (8) (Grimes, 1970).

If the UF_4/UF_3 ratio is not sufficiently high, metallic U can deposit on surfaces within the reactor and subsequently react with the moderator graphite and structural alloys. Maintenance of a proper UF_4/UF_3 ratio for redox control was achieved in MSRE by periodic immersion of a beryllium rod, an active reducing element, with the salt, via Reaction (9) (Thoma, 1971).

Due to the slight solubility of Be metal in FLiBe, this control strategy had the benefit of being able to control the redox state of the salt in a distributed manner, rather than in a discrete location that may occur when using reducing metals that are insoluble in salts.

For redox control in chloride salts, the $\text{U}^{3+}/\text{U}^{4+}$ ratio is also considered as one of the primary control mechanisms. However, because there is higher relative stability of UCl_3 in comparison with UF_3 , much lower $\text{UCl}_4/\text{UCl}_3$ ratios of roughly 0.003–0.05:1 are expected to minimize the corrosion of nickel-based structural alloys (Holcomb, 2017). The presence of a small amount of UCl_4 can help inhibit the disproportionation reaction of UCl_3 to U and UCl_4 . However, experimental validation is needed to verify and identify the ideal $\text{UCl}_4/\text{UCl}_3$ ratio range for long-term chloride salt-fueled MSR operation.

Conclusions

The discussion above on the various neutronic, thermophysical, chemical and materials compatibility properties of molten salt systems is intended to serve as an overview of the physical phenomena that must be understood for the design and operation of an MSR, and the state of knowledge in the fields as of the date of publishing. Much more detail on each of these properties is available in the literature sources cited, as well as in many other journal articles, book chapters, and reports that were not included here. Recent renewed interest in advanced nuclear reactors, and MSRs specifically, has significantly accelerated the rate at which the knowledge base for the topics discussed in this report is expanding, necessitating those interested in MSR development to remain diligent about maintaining an up-to-date understanding of the research that has been recently conducted. The reader is thus encouraged to use this report as a jumping off point to explore the intricacies and nuances of the details of molten salt systems and molten salt reactors.

Glossary

Burnup A term used to quantify how much ^{235}U has fissioned. The commercial industry quantifies burnup in terms of power (MWd/kgU or GWd/MTU).

Dislocation A line defect within the atomic lattice of crystalline materials. It is most often thought of as an extra partial plane of atoms in the lattice. Movement of dislocations are the underlying mechanism for plasticity and high strain-rate creep.

Lattice The periodic arrangement of atoms in crystalline materials.

LHGR Linear heat generation rate—power generated per unit length of fuel rod.

Reactivity Reactivity is a measure of deviation from criticality—the state in which the rate of neutron generation from fissioning equals the rate of neutron losses.

SAFDL Specified acceptable fuel design limit (SAFDL) is a term used by the Nuclear Regulatory Commission to communicate a fuel performance limit that is acceptable for showing regulatory compliance. For example, one fuel performance SAFDL is that fuel melting will not occur.

Washout When fuel degradation occurs after a fuel failure, large open axial cracks can occur exposing surface area of the fuel pellets to the coolant. When this happens, the fuel oxidizes further, and small pieces become entrained in the coolant. This process of losing fuel to the coolant is called washout. Fuel degradation is uncommon today.

Introduction

Light-water reactor (LWR) fuel is elegant in its simplicity. The fuel is in the form of ceramic uranium dioxide (UO_2) cylindrical pellets with an approximate 1:1 length-to-diameter ratio that are contained in a thin-walled tube made of a zirconium alloy called the cladding (see Fig. 1). The relative content of fissile ^{235}U ranges from natural (0.71% ^{235}U) to as high as 5% enriched. These fuel rods are then assembled into square-array bundles (or assemblies). Over time the fuel rod diameters have decreased, which decreased the linear heat generation rate (LHGR) for given rods while the number of rods per assembly has increased, maintaining bundle powers and enabling increased bundle powers. In boiling water reactors (BWRs), the fuel bundles were initially a 6×6 square array of fuel rods but the number of fuel rods in an assembly increased over time to improve performance. Modern fuel is 10×10 with some fuel vendors introducing 11×11 fuel designs. Unlike BWRs, the array size of pressurized water reactor (PWR) fuel is static for each specific reactor design. In some of the older plant designs, the array size is 14×14 or 15×15 while the newer designs use 17×17 fuel. For perspective, the fuel rod diameters of BWR 11×11 fuel is comparable to PWR 17×17 fuel (~ 9.5 mm), so the PWR fuel assemblies are larger with a greater number of comparably-sized fuel rods. Another difference between BWR and PWR fuel is the channel box or fuel channel surrounding each BWR fuel bundle. The channel box eliminates cross flow and creates a gap between the fuel assemblies where water does not boil, providing neutronic benefits.

The process of manufacturing a nuclear fuel rod starts with fabricating UO_2 fuel pellets. The first step in this process is the conversion of uranium hexafluoride (UF_6) gas into UO_2 powders. The powders are then blended to the desired enrichment, pressed into a cylindrical pellet and sintered to a very high density (95–98% theoretical density). The physical differences between PWR and BWR fuel pellets (diameter, density, enrichment and microstructure) have only a minor effect on fuel performance.

One important lesson learned from the early days of manufacturing LWR fuel is that open porosity should be minimized. Open porosity refers to connected pores that provide pathways to the surface of the pellet, while closed porosity refers to isolated pores inside the pellet. The problem with open porosity was that it created large surface areas where moisture could be adsorbed prior to pellet insertion into the cladding tubes. This moisture was then released and/or radiolyzed during irradiation, reacting with the inner surface of the cladding, releasing hydrogen that was then absorbed in the cladding, causing primary hydride failures. Today, pellet specifications limit the amount of open porosity and moisture content in the pellets.

Traditionally LWR fuel cladding has been fabricated from a zirconium alloy, although there were some very early fuel rod designs that used stainless steel as the cladding material. Zirconium alloys were developed as structural materials for in-reactor applications within the Navy Nuclear Propulsion program in the United States during the early 1950s. In 1952, Westinghouse patented

Fig. 1 Schematic of a typical LWR fuel rod.

a zirconium alloy they called Zircaloy-2, which is ~98% zirconium with additions of tin, iron, chromium and nickel. Soon after, various zirconium-niobium alloys were also developed in Russia and England. The use of zirconium as a cladding material was driven by the low thermal-neutron absorption cross section of zirconium and the good corrosion resistance and structural performance in LWR conditions.

The development of zirconium cladding materials since the 1950s has been different for BWRs (Hamon, 2021) and PWRs (Brown, 2021). PWR fuel primarily used an alloy called Zircaloy-4 until the late 1990s when various zirconium-niobium alloys were introduced, while BWR fuel vendors still universally use Zircaloy-2 for the cladding (though with optimized chemistry and processing compared to early Zircaloy-2). The primary reason for the difference between BWR and PWR cladding is that the water chemistry in a BWR is oxidizing while in a PWR it is reducing. However, while there have been different solutions to cladding development, the development in both BWRs and PWRs was driven mainly by the desire to improve corrosion resistance and decrease the pickup of corrosion-generated hydrogen into the cladding. Looking ahead, cladding development is moving toward adding coatings to further improve corrosion and hydrogen pickup performance of zirconium alloys and even non-zirconium materials are being considered.

Although simple in concept, one reason LWR fuel is such an interesting technology is the diversity of knowledge needed to understand its irradiation performance. From the nuclear engineering perspective, understanding the fission process within the fuel is important because it is the fundamental phenomenon that drives all other considerations. There is also the need to understand the plant operations that define the performance requirements, including normal steady-state operations, anticipated transient events (or anticipated operational occurrences, AOOs), and design basis accidents (DBAs). From the mechanical engineering perspective, nuclear fuel is a problem of getting heat from the ceramic UO_2 fuel through the metal zirconium alloy cladding to the hot and pressurized water coolant while maintaining the mechanical integrity of the fuel rod throughout life. And from the materials science perspective, one must understand the effect of the fission process on the properties of UO_2 fuel, the effect of the neutron flux on the properties of the zirconium alloy cladding and other structural components, and the effect of the highly corrosive water on the component surfaces. These issues have filled the careers of many engineers over the last 70 years.

Given the vast data and knowledge regarding LWR fuel, the following can only be an introduction to the important aspects of the irradiation performance of LWR fuel. In the next section the performance requirements are discussed from a regulatory perspective. Then for each type of operation, the fuel performance requirements and phenomena are discussed in detail: normal steady-state operation is covered in section “**Normal operation performance**,” anticipated transient events in section “**Anticipated transient performance**” and design basis accidents in section “**Design-basis accident performance**.” Section “**Fuel performance analyses**” provides a short discussion of the fuel performance analyses needed to show compliance to regulatory requirements, and the final section provides a summary.

Performance requirements

The primary objective for commercial reactors is safe generation of power. Safe operation is always defined in the context of safety to plant workers and the public living and working around the plant. The fuel rod is the first of three barriers that protect workers and the public from the highly radioactive isotopes in the fuel. The two other barriers are the reactor pressure vessel and the containment structure. Therefore, regulators either define or provide guidance on the fuel performance requirements to ensure fuel failure (i.e., breach of the cladding) does not occur or to explicitly account for fuel failures to ensure there is no safety impact (Rempe, 2021). As an example, the US Nuclear Regulatory Commission (NRC) has issued NUREG-800 Standard Review Plan (SRP), Section 4.2 (USNRC, 1987), which defines Specified Acceptable Fuel Design Limits (SAFDLs) that can be used to confirm a fuel design will operate safely. SAFDLs of primary importance for fuel rods during normal operation and anticipated transients are those that address fuel rod temperature, cladding strain and fuel rod internal pressure.

The first and most important fuel performance requirement is to prevent cladding failure and the potential release of gaseous fission products or fuel washout. This is done by limiting the cladding strain under low strain-rate conditions that occur during normal operation and high strain-rate conditions during the anticipated transient events and design basis accidents. As discussed in the following sections, the strain limits are not challenged under normal operating conditions but are during the transient and accident events.

The second requirement is to avoid fuel melting, particularly during normal operation and anticipated transients. Thus, reactor operation must be controlled to ensure the temperature of the center of the fuel pellet remains less than the melting temperature of the UO_2 fuel, which is a function of the specified as-fabricated chemistry and the changes in chemistry due to accumulation of fission products. Because fuel centerline temperature will follow power level, the avoidance of fuel melting limits the fuel power (i.e., the LHGR) that can be experienced in anticipated transient events, which in turn limits LHGR during normal operation.

The third requirement is to limit fuel rod internal pressure. During normal operation, gaseous fission products (primarily Xe and Kr) are released to the fuel rod void space, resulting in an increase in rod internal pressure. The pressure is limited to prevent large cladding diametral strains and possible cladding failure. The limit on fuel rod internal pressure is a concern during normal operation. The size of the plenum region in the fuel rod is a variable that helps manage rod internal pressure.

For DBAs, fuel rod failure is permitted so the fuel performance requirements are defined to minimize the number of failed rods and their effects. In the loss-of-coolant accident (LOCA), the purpose of fuel performance limits is to ensure that when water is added to the reactor to replace lost coolant the fuel rods can be effectively cooled. For example, the NRC limits cladding

temperature, cladding oxidation, and hydrogen generation from cladding oxidation (see 10 CFR Part 50.46) to avoid flow blockage because of clad ballooning when temperatures increase and fuel rod fragmentation (i.e., the fracture of a fuel rod into pieces) when temperature decreases rapidly during quench. The other accident that impacts the fuel is the reactivity-initiated accident (RIA). This accident is a special kind of power transient, and thus, similar to the anticipated transients, the performance requirements are defined relative to mainly cladding strain and fuel temperature.

In addition to meeting the regulatory requirements, fuel rods are designed to assure high reliability and to meet specific performance and operation requirements, including those on power density, neutron flux range, temperature range, lifetime, and fuel cycle economics.

Normal operation performance

Normal operation includes steady-state performance where the power is generally held constant (or at steady state), start up, cool down and any power changes that are initiated in the control room. During start up, the reactor pressure is increased to operating pressure and the water is pre-heated to nearly operating temperatures. The control rods are then removed slowly until fissioning starts to occur in the fuel pellet, adding heat to the system and increasing the intensity of the neutron cloud (or flux) that feeds further fissioning. When the reactor is at power, there are axial and radial power distributions across the core. The radial distribution is such that the bundles in the outer periphery are at a lower power than bundles in the center region of the core. Axially in BWRs the power distribution is initially peaked at the bottom but transitions to top peaked over the operation time in the cycle. In PWRs the axial distribution is not as peaked and does not change as significantly during operation. Lastly there can be power distributions within the fuel rods of a single bundle. This is more prevalent in BWRs because of the water gaps between the bundles, which increase moderation near the edge rods. An effect of this variability in power is that there will be a small number of locations in the core that experience limiting fuel performance conditions during operation, and these locations may change during the cycle.

The main difference between the PWR and BWR plant designs, with regard to fuel performance, is the pressure and temperature of the reactor water. BWRs are operated at a reactor pressure of ~ 7 MPa, and the coolant temperature along the length of the fuel is a constant 288°C . In contrast, the PWR is operated at approximately twice that pressure (~ 14 MPa) and the temperature increases from $\sim 280^\circ\text{C}$ at the inlet to $\sim 315^\circ\text{C}$ at the outlet. The constant axial temperature in BWRs is a result of meeting the boiling condition at all elevations except for inlet region at the lower portion of the bundle where the water temperature is somewhat lower. In PWRs, the high pressure suppresses boiling creating a thermal hydraulic condition allowing the water temperature to increase axially along the length of the fuel rod. The impact of these differences is that the cladding temperature is higher in a PWR than a BWR. Therefore, cladding phenomena driven by temperature (like cladding corrosion and hydrogen pickup) are more severe in a PWR than a BWR.

As discussed in section “**Performance requirements**,” the one fuel performance requirement that is challenged during steady-state operation is fuel rod internal pressure. The purpose of this performance limit is to avoid excessive creep strain in the cladding, which could cause rupture. There are two common ways to ensure the cladding does not rupture during normal operation. The most conservative approach is to limit the rod internal pressure to the coolant pressure of the reactor vessel, making large creep strain deformation impossible. The second approach is to limit the rod internal pressure to a value that assures the cladding will not creep out faster than the fuel is swelling. This limit prevents the outward creep of the cladding away from the fuel surface (i.e., cladding liftoff), which increases heat transfer resistance and raises fuel temperature, causing further fission gas release and creep out.

Fuel performance phenomena in steady state

Before fuel-rod performance can be predicted for steady-state operations, the underlying physical phenomena that occur during operation must be understood. This understanding then allows mechanistic, phenomenological or empirical models to be incorporated into an integrated fuel-rod model that will predict both the thermal and mechanical response of the fuel rod. The fuel pellet is the more complex part to model. The thermal stresses that are generated during start up cause the pellet to expand and fracture. Then over time, the accumulation of fissions (referred to in the industry as fuel burnup) causes changes in the fuel pellet with the introduction of fission products (both solid and gaseous). The fission products cause pellet swelling. The high temperatures inside the pellet result in fuel pellet densification, particularly for pellets with high initial porosity. In addition, the gaseous fission products eventually collect into fission gas bubbles and are partially released over time to the void space in the fuel rod. The expansion of the pellet from thermal expansion and fission-induced swelling combined with the internal gas pressure eventually causes pellet cladding mechanical interaction (PCMI), which in turn causes expansion of the cladding diameter. Finally, distribution of fission rate through the fuel pellet results in a distribution in burnup within the fuel. This causes greater changes in the microstructure of the pellet rim (where the power and burnup are highest) creating what is commonly referred to as a high-burnup rim structure. Fuel burnup is the main source of physical changes to the pellet, and effects of the fast neutron flux combined with PCMI induce the greatest cladding geometry and material properties changes. The fast neutron flux causes irradiation hardening, irradiation growth and irradiation creep and enhances corrosion, which has the result of increasing hydrogen pickup. The following sections provide a detailed description of these pellet and cladding phenomena during steady-state operations.

Fuel pellet performance phenomena

A fuel rod is manufactured by inserting sintered UO_2 pellets into a zirconium alloy tube, and then welding zirconium alloy plugs on both ends to hermetically seal the tube. Generally, there is an unfueled length at the top of the rod, referred to as a plenum, intended to accommodate released fission gases. The environment inside the rods is pressurized helium. To ensure that fuel pellets can be loaded into the cladding tube by automated rod loaders there is a gap between the pellets and the tube (~ 0.1 mm). This is the condition of a fuel rod at the start of operation.

The fission process

There are really two phenomena to consider when thinking about the fission process occurring within UO_2 fuel pellets. The first is the fission event itself, where a thermal neutron is absorbed by a ^{235}U atom causing ~ 200 MeV energy to be released—most as kinetic energy when the uranium atom splits into fission products. The second phenomenon is the conversion of the fission-product kinetic energy to heat energy within the crystalline lattice of a ceramic fuel pellet. This process is illustrated using the simplified UO_2 lattice of Fig. 2. After the fission event occurs (see Fig. 2A), the fission products are ejected from the original lattice site creating a damage path in their wake, eventually settling into a substitutional or interstitial uranium lattice site (see Fig. 2B). The damage to the lattice is quickly “healed” as most of the atoms knocked out of their lattice sites return. However, at the end of this process (which is on the order of picoseconds), some point defects will remain (see Fig. 2C).

The distribution of fission products varies mainly between elements with mass numbers of 75 and 160. In addition, because of radioactive decay of most fission products, the distribution is constantly evolving. For the purposes of fuel performance, the fission products can be characterized as either solid or gaseous. All fission products contribute to solid fuel swelling initially; the gaseous fission products may combine into bubbles which further drive swelling and can be released from the fuel to increase the rod internal pressure or cause a chemical degradation of the cladding.

Fuel pellet cracking and relocation

When the power increases in a fresh rod, the pellets heat up. A strong temperature gradient inside the pellet forms with the center of the pellet having the highest temperature (see Fig. 3). Because thermal expansion will follow temperature, the pellet volume near the center of the pellet will increase more than the volume near the pellet surface, which creates radial and axial gradients of thermal strain and stress, ultimately causing the pellets to fracture into smaller pieces due to radial and transverse cracks. The shapes of these pieces are idealized as wedges in Fig. 4A, considering the thermal strains and resulting stresses run in both the hoop and axial directions. The rapid energy release associated with this pellet cracking can result in relative motion of the pellet pieces filling the gap between the pellet and cladding. Such motion may also occur due to forces from the cladding being applied to the pellet pieces. This motion is referred to as “relocation.” Because sintering during normal operation may heal cracks created during the initial power rise, this phenomenon of cracking and relocation may also occur during subsequent power rises. As described above, relocation is assumed to transfer gap volume to internal pellet cracks. Thus, relocation is assumed to occur only at fuel burnups where a theoretical gap may exist.

Fuel densification and swelling

Fuel densification during normal operation can be thought of as a continuation of the sintering process used to fabricate the pellets to 95–98% of theoretical density. Sintering is a specific type of heat treatment of materials—usually ceramics—which is used to densify packed-powder structures into nearly fully dense components. The driving force for this densification is the transformation of the high-energy surface areas of the powders being sintered to low energy grain boundaries. The rearrangement of the atoms occurs via thermal diffusion, thus the need for high temperatures. During in-reactor operation, diffusion of uranium and oxygen continue because of temperature. At 100% power the range of temperatures from the outer surface to the center is ~ 500 °C to

Fig. 2 A schematic illustration of the fission process in a UO_2 lattice. (For simplicity, the oxygen atoms are not shown.) (A) Fission, (B) fission damage, and (C) point defects created after “healing” of fission damage.

Fig. 3 Schematic of the profile of temperature and fission gas release in a fuel pellet during normal operations. Fuel microstructure images from Garcia P, Martin G, Sabathier C, Carlot G, Martin P, Dorado B, Freyss M, Bertolus M, Skorek R, Noirot J, Noirot L, Kaitasov O, Maillard S (2012) Nucleation and growth of intragranular defect and insoluble atom clusters in nuclear oxide fuel. *Nuclear Instruments and Methods in Physics B* 277, 98–108.

Fig. 4 Simplified schematic representation of various fuel pellet phenomena. (A) Fuel pellet cracking, (B) intragranular fission gas bubble at atomistic level, (C) intergranular fission gas bubble at atomistic level, and (D) intergranular and intragranular fission gas bubbles at microscopic level.

~1800 °C. But diffusion will also occur when atoms are displaced by fast neutron bombardment or by recoiling fission fragments. This nuclear energy is then added to the thermal energy in the pellet making densification via in-reactor sintering easier than out of reactor. In addition to sintering causing fuel densification, it will also “heal” cracks created during power rises; that is, the crack surfaces may rebond.

However, sintering is not the only mechanism for densification. Fuel densification will also occur because of hot-pressing which is the simultaneous application of high temperature and stress. During in-reactor operation when fission occurs and a ^{235}U atom splits, the resulting fission products will occupy a greater volume than the original ^{235}U atom. As shown in Fig. 2C, the result of a fission event is one more atom in the lattice and additional point defects. The reality is of course much more complex than shown in Fig. 2 as the various fission products behave differently (some being stable within the UO_2 lattice while others form second phase

particles) and point defects are also being created in the oxygen lattice. These lattice defects cause a local volume increase, resulting in a local stress field around the defect. As this internal stress builds up, it increases the driving force for diffusion into as-fabricated porosity causing further densification.

Once the as-manufactured porosity is eliminated by either sintering or stress-induced diffusion, the volume change associated with the creation of fission products in the UO_2 lattice causes the macroscopic dimensions of the pellet to increase. This apparent swelling is usually referred to as solid swelling. Two important fission products are Xenon and Krypton, which are noble gases. Like other fission products, these elements will contribute to solid swelling when they are created. But unlike other fission products, these elements can eventually collect together to form fission gas bubbles—either inside grains as intra-granular bubbles (Fig. 4B) or between grains as inter-granular bubbles (Fig. 4C). However, because solid swelling models are generally empirical and based on macroscopic measurements of pellet swelling, any volume change associated with the precipitation of fission gas into bubbles is already accounted for in the data. This volume change is also a function of the hydrostatic stress state on the pellet due to the PCMI between the pellet and cladding, which is extremely complex and difficult to model. Thus, most fuel performance models will not explicitly account for the formation of fission gas bubbles in their swelling models. Fission gas swelling separate from solid swelling is treated empirically in some models. Fission gas swelling will be considered again when discussing transients where burnup-driven solid swelling is not a factor.

Fission gas release

In addition to contributing to burnup-driven swelling, whenever Xenon or Krypton atoms reach a free surface, the gas atoms will be released to the fuel rod volume causing an increase in the internal gas pressure of the fuel rod. To reach free surfaces, which could be the outer surface of the pellet or a crack created during a power increase, the fission gas atoms must diffuse from their creation sites through the UO_2 lattice. (When a fission event occurs near a free surface, the resulting fission gas atom may be ejected directly into the free volume. This mechanism accounts for a very small percentage of fission gas release and is not discussed further.) While some fission gas is released by diffusing directly to a free surface, the majority of fission gas is released through a two-step process. Step 1: fission gas diffuses through the lattice to grain boundaries where inter-granular fission gas bubbles precipitate and grow. The lattice diffusion step is highly dependent on temperature—increasing as temperature increases. Step 2: over time as burnup increases, these inter-granular bubbles will eventually coalesce (see Fig. 4D). When significant coalescence occurs and fission gas bubbles grow large enough to interconnect, a continuous path to a free surface can be created causing a small burst of fission gas release. This process of fission gas release through interconnected inter-granular bubbles is dependent on temperature, burnup, grain boundary strength, hydrostatic stress on the pellet due to PCMI and the diffusion coefficient of the gas atoms in the solid pellet. Based on empirical data, there appears to be an burnup-dependent temperature threshold for the release of fission gas by this coalescence mechanism. The implication of these observations is that fission gas is not released uniformly throughout the pellet. Because there is a large temperature distribution in the pellet, the majority of fission gas will be released in the higher temperature parts near the center of the pellet. As the temperature decreases toward the outer radius of the pellet, diffusion rates decrease, and it becomes less likely that fission gas will find grain boundaries and more likely that fission gas atoms will find like atoms and precipitate into intra-granular fission gas bubbles, effectively trapping the gas atoms from release to a free surface.

The process of fission gas release described above is shown in Fig. 3 as a function of relative radius. Near the center of the pellet, both the inter-granular and intra-granular bubbles are μm -scale in size and visible at typical magnifications used in a scanning electron microscope (SEM). Coalescence of these inter-granular bubbles produces the largest fission gas release. As the temperatures in the pellet decrease, there is so little diffusion that the bubbles remain nanometer size and are not visible at typical SEM magnifications. Most of the fission gas will be trapped in small intra-granular bubbles and there is little fission gas release. Near the periphery of the pellet, where the temperatures are the lowest and the burnup is the highest, due to enhanced creation of plutonium (via the self-shielding phenomenon), there is a transformation to the so-called high-burnup structure (HBS) (Garcia et al., 2012). The process of transforming from an intra-granular dominated microstructure to a high-burnup structure is still not well known. What is known is that a larger-grain structure with nanometer-size intra-granular bubbles transforms into a subgrain structure with large fission gas bubbles, where the large fission gas bubbles are surrounded by many subgrains. There is very little fission gas within the lattice of HBS; all the fission gas has been swept into the large fission gas bubbles during the transformation process. Interestingly, the transformation process that causes a large redistribution of fission gas does not result in a significant increase in fission gas release; like the intra-granular dominated region, little fission gas is released in the HBS region during normal operation. The release of fission gas from the HBS region will be discussed again in the context of design basis accident scenarios (see section “Design-basis accident performance”).

Cladding performance phenomena

During normal operations, the zirconium-alloy cladding must maintain integrity while being exposed to high-temperature, high-pressure water and bombarded by neutrons. The impacts of neutron bombardment are phenomena called irradiation hardening and irradiation growth. When the neutron bombardment is added to high-temperature and high-pressure conditions, irradiation creep occurs. Because all this happens within a water environment, corrosion of the cladding and the subsequent absorption of hydrogen from the oxidation process are important considerations for the performance of the cladding. These phenomena also affect the cladding response to applied stress due to coolant pressure, rod internal pressure and pellet-cladding mechanical interaction.

Irradiation hardening

Irradiation hardening and irradiation growth are material phenomena that are unique to a nuclear reactor environment. The high-energy neutrons that are emitted by the fission process will also interact with any surrounding structural material like the cladding. The high-energy neutrons collide with atoms in these materials creating what are called collision cascades—similar to the fission damage cascade represented in Fig. 2C. The atom that is hit careens through the lattice knocking other neighboring atoms out of their normal lattice sites and into interstitial sites. Each time an atom is knocked out of its lattice site, one vacancy and one interstitial defect is created. Subsequent collisions decrease the energy of the original atom making the next collision less energetic. Once the process stops, the original atom will be in an interstitial site and there is a path of vacancies and interstitials in the wake.

The majority of the new interstitial atoms will recombine with a neighboring vacancy, “healing” the defected structure. But some percentage of the defects become permanent (see Fig. 5A). These new point defects will diffuse through the lattice and eventually find other like defects to combine with to form plate-like defects called dislocation loops (either as vacancy or interstitial loops, see Fig. 5B) or deposit onto grain boundaries. The dislocation loops are effectively “hard” spots in the lattice that limit dislocation motion due to slip, which results in an increased yield strength. Over time as the fluence (or time-integrated neutron flux or neutrons/cm²) increases the dislocation loop population, the yield strength will increase (i.e., the material hardens), eventually saturating once the defect structure saturates. Another common quantity of neutron damage is displacements per atom (dpa), which is a measure of the number of atomic displacements each atom might receive upon an amount of neutron exposure. This saturation in irradiation hardness of the cladding occurs during the first cycle of operation when the neutron damage is ~ 3 dpa. A typical neutron damage in the cladding at the end-of-life in an LWR is between 10 and 12 dpa. What this means is that every atom in the cladding is displaced by a neutron 10–12 times in the lifetime of the fuel—highlighting how challenging the environment is in a nuclear reactor.

Irradiation growth and irradiation creep

The creation of point defects from neutron collisions followed by redistribution is also the source for irradiation growth and irradiation creep. Irradiation growth occurs because diffusion is faster along certain planes within the hexagonal closed packed (HCP) crystal structure. Interstitial atoms prefer the prism planes while vacancies prefer the basal planes (i.e., the energy barriers to atomic jumps are lower for interstitials in prism planes and for vacancies in basal planes). What this means is that the plate-like defects that are the source of irradiation hardening will preferentially form on certain types of planes in the crystal structure: interstitial loops on prism planes, which expand the lattice, and vacancy loops on basal planes, which contract the lattice. Thus, the differential diffusion causes the grains to change shape, expanding perpendicular to the prism planes and contracting perpendicular to the basal planes. If the orientation of grains was randomly distributed in space, the expansion and contractions would cancel each other out and there would be no observed macroscopic growth. However, because zirconium alloys have an HCP crystal structure, the normal processing routes for cladding cause most of the grains in the microstructure of the cladding tube to have a similar orientation; the material is said to have a texture. In the case of zirconium-alloy cladding, the texture is such that the material exhibits irradiation growth in the axial and transverse directions but contracts in the radial or thickness direction. Because irradiation growth occurs without any applied stress it is sometimes referred to as stress-free growth.

Irradiation creep is the time-dependent deformation of zirconium alloys under an applied stress that is below the yield stress during neutron radiation exposure; deformation at stresses beyond the yield (i.e., plastic deformation) is considered time-independent deformation. The most common analytic model for creep in unirradiated materials is the power-law model. In this model, the steady-state creep rate ($\dot{\epsilon}$) is $\dot{\epsilon} = K(T)\sigma^n$ where $K(T)$ is a temperature-dependent function (usually an Arrhenius-type function), σ is stress and n is the stress exponent. Typically, at low stress, n is 1, while at higher stress it increases to 4–7. The change in the exponent indicates a change in the dominant mechanism. At high stress (approaching the yield stress), the mechanism of irradiation creep is generally thought to be similar to out-of-reactor thermal creep. That is, creep at high stresses is driven by diffusion-controlled dislocation motion. However, because of irradiation hardening, irradiation creep in the high-stress regime is lower than thermal creep of unirradiated cladding.

In contrast, at low stress, irradiation creep is enhanced compared to thermal creep. In this stress regime the creep rate is linearly proportional to stress (i.e., $\dot{\epsilon} = K(T)\sigma$). The mechanisms of thermal creep in this stress regime might be referred to as grain shape-

Fig. 5 Simplified representation of irradiation damage in a zirconium lattice. (A) Vacancy and interstitial point defects in a zirconium lattice and (B) vacancy and interstitial dislocation loop defects.

changing mechanisms; grains change shapes because of diffusion driven by internal stress distributions in the grain. For thermal creep, when diffusion is dominant along grain boundaries, the creep mechanism is referred to as Coble creep. When diffusion is through the grain volume, the mechanism is known as Nabarro-Herring creep. Irradiation creep at low stress is generally thought to be a grain shape-changing mechanism like Coble creep or Nabarro-Herring creep, but by a different mechanism—most likely a stress-enhancement of the irradiation growth mechanism. That is, stress enhances the growth of the interstitial and vacancy loops that are a result of irradiation damage.

Corrosion and hydrogen pickup

One of the most important performance criteria for LWR cladding is a general resistance to corrosion during in-reactor operation. Corrosion is the oxidation of the cladding via the decomposition of water. The chemical reaction is given by $\text{Zr} + 2\text{H}_2\text{O} \leftrightarrow \text{ZrO}_2 + 2\text{H}_2$. The zirconium oxide becomes a thin corrosion film on the outer surface of the cladding, while the hydrogen is either released into the coolant or absorbed into the cladding. Hydrogen pickup (absorption) by the cladding is typically a small fraction (0.1–0.2) of the hydrogen generated.

Corrosion resistance (i.e., resistance to oxidation) is important for two reasons. First, in the mechanical design of a fuel rod, the metal loss from corrosion must be considered, and second, the predicted fuel temperature must account for the resistance of the corrosion film to heat transfer. Thus, minimizing corrosion maximizes the cladding thickness available to resist internal gas pressure and minimizes the fuel centerline temperature at a given power (which maximizes the power associated with the prediction of the temperature to fuel melt).

Absorption of hydrogen (i.e., hydrogen pickup) is a side effect of the corrosion process. The problem with hydrogen is that it has an embrittling effect on the cladding. This occurs because of the formation of zirconium hydrides, which are generally considered a brittle phase. Another negative impact of hydrogen pickup is the volume increase in the formation of zirconium hydride. Concentration of hydrogen can thus cause a hydride bulge in the cladding. The volume change causes large internal cladding stresses and these locations become weak spots that are susceptible to failure (cladding breach) during normal power increases. Additionally, the volume change associated with hydrogen absorption can result in assembly bow if hydrogen occurs non-uniformly within the assembly. In BWRs, such bow by fuel channels has the potential to impede control rod insertion (Cantonwine et al., 2009).

More than anything, the development of cladding materials for LWR applications has been driven by the desire to improve corrosion resistance and hydrogen pickup. The whole development of the Zircaloy family of alloys in the 1950s was linked to improvements in both corrosion and hydrogen pickup; Zircaloy-2 for corrosion and Zircaloy-4 for both corrosion and hydrogen pickup. Decades of work on the effects of irradiation, cladding chemistry and microstructure are largely documented in the ASTM series on Zirconium in the Nuclear Industry. The result of these decades of work today is the excellent performance of cladding in both BWRs and PWRs. Looking ahead, one of the main advantages for potential coatings on zirconium-alloy cladding is the improved corrosion and hydrogen pickup performance.

Interactions between the pellet and cladding

The most important function of the fuel rod is to transfer heat generated in the fuel pellet to the coolant outside the cladding. The more effectively heat is transferred, the lower the fuel temperatures. At the beginning of life, the pathway of the heat is through the fuel pellet, across the ~ 0.1 mm gap between the fuel pellet and the cladding, through the cladding and out into the coolant. The initial thermal conductivity of the fuel is a function of the as-sintered density but changes with burnup because of lower thermal conductivity fission products and the development of fission gas bubbles. The burnup dependence of the thermal conductivity is often expressed as a function of swelling through its dependency on porosity. The result is a reduction in thermal conductivity with burnup that can be as large as 20% at end of life. Cracking and relocation introduce crack surfaces and internal gaps that can also degrade thermal conductivity especially when oriented circumferentially. The thermal resistance of the gap is a function of the gap size and the thermal conductivity of the gas atoms occupying the gap. At beginning of life, the thermal resistance of the gap is minimized by filling the rod with pressurized helium, which has a much higher thermal conductivity than air. However, the thermal resistance increases with the release of fission gas with increasing burnup but decreases as the gap closes via swelling of the fuel and creep down of the cladding. Like the degradation in thermal conductivity in the fuel with burnup, the changes in thermal conductivity of the gap are accounted for in the thermal analysis of the rod.

After the gap is closed during steady-state operation, further expansion of the pellet from fission-induced swelling causes the cladding diameter to increase with burnup. This type of interaction is referred to as Pellet Cladding Mechanical Interaction (PCMI). Because the fission-induced swelling rate is low, the strain capacity of the cladding is large, and failure of the cladding by PCMI during steady-state operation does not occur. However, there is a chemical interaction that can occur and cause failure during normal operation. When there is a localized power increase in an area of the reactor core, due mainly to pulling out a control rod, there is an immediate increase in temperature of the pellet and some fission gas is released. While the fission gas is mostly Xe and Kr, it also contains iodine, which is known to cause stress corrosion cracking in zirconium alloys. Thus, when the cladding stress is high enough and the power change and rate of power change is large enough, iodine stress corrosion cracking can cause fuel failure. Because this failure is always associated with a normal power change, it is generally referred to as a “duty” failure. In addition, to distinguish this phenomenon from PCMI, these duty failures are said to be caused by Pellet Cladding Interaction (PCI) or sometimes Pellet Cladding Chemical Interaction (PCCI). These failures typically occur at low cladding plastic strain and well below the 1% strain limit used for PCMI in anticipated transients (see section “PCMI failure”).

Duty failures were a significant issue in the 1970s and 1980s (mainly in BWRs) until an understanding of PCI was developed and mitigating actions were taken. BWRs were more susceptible to PCI because control rods are used more to control power through an operating cycle than in PWRs, which use boron in the primary coolant to manage reactivity through the operating cycle. Because of this there is more control rod motion during normal operation in BWRs than in PWRs. The mitigation of PCI has entailed both design changes to the fuel and operational changes at the plants. The development of barrier fuel, which adds a thin layer of less-susceptible, dilute zirconium alloy to the inside diameter of the cladding, significantly decreased failures attributed to PCI. In addition, operating guidelines have been developed for plant operations to better control the rate of local power changes when moving control rods; therefore, decreasing the amount of fresh iodine released and the stress applied to the cladding.

Anticipated transient performance

Fuel rods are designed and licensed to withstand the effects of transients during normal operation. These transients are sometimes called anticipated operational occurrences (AOOs). The frequency of performance limiting anticipated transients is low (~ 1 per reactor lifetime). There are two types of anticipated transients, either core-wide or localized. The most common core-wide anticipated transient is due to a pressurization transient. A pressurization transient is a rapid increase in coolant pressure that causes a short duration rapid power increase. The power increase can be several times the normal operating power, and the duration is typically 1–2 s, which is much shorter than the fuel rod thermal time constant (< 10 s for modern LWR fuel). With these time constants, it takes ~ 30 s to reach the equilibrium temperature distribution at the maximum power in the transient. Thus, the maximum fuel temperature at the center of the pellet will lag the power increase. This type of anticipated transient is often referred to as a fast transient and a generic example is shown in Fig. 6. Localized anticipated transients are typically due to operator actions taken to achieve specific operational targets. In BWRs, these anticipated transients are often referred to as rod-withdrawal errors (RWEs). Localized events typically have longer duration (larger than the thermal time constant) and smaller power increases than core-wide events such that the temperature increases coincidentally with the power.

By their nature, anticipated transients are more severe than power increases during normal operation. Depending upon operation, the peak power allowed in an anticipated transient is limited either by the fuel rod temperature or cladding strain. When temperature is limiting, the allowable peak power is defined such that the temperature at the center of the pellet is less than the melting temperature of the UO_2 fuel. When strain is controlling, the allowable peak power increase is limited to maintain a cladding strain increment below a failure threshold, which is typically 1%.

Performance phenomena in an anticipated transients

Two features of an anticipated transient event drive what phenomena need to be considered in predicting performance. Those two features are the change in power and the time over which the power change occurs. The fuel pellet expands with the increase in power mainly by thermal expansion, but at high burnups fission gas swelling may also be a contributor. The expansion of the pellet results in a corresponding loading of the cladding material by PCMI. The strain rates in the cladding during a transient are

Fig. 6 An example of a fast transient where the event is shorter than the thermal time constant of the fuel rod—meaning the temperature increase in the fuel and the cladding will lag the power increase.

considered to be consistent with time-independent deformation mechanisms (i.e., plasticity). Transient response is determined by the duration of the transient relative to the fuel time constant. For fast transients, when there is a delay in the temperature response relative to the peak power, the full fuel thermal expansion corresponding to the peak power is not applied to the cladding because the equilibrium temperature distribution associated with the peak power is not reached.

Fuel melting

Although the phenomenon of melting is well understood, the conditions of melting in a fuel rod are unique because the heating is internal rather than external. Melting can only occur when the temperature exceeds the melting temperature, which for an anticipated transient is reached first in the center of the fuel pellet. The melt volume would be limited to this area of the pellet because of the radial and axial temperature gradients. That is, there would be no migration of the melted fuel radially or axially—meaning melting does not propagate. The axial temperature gradients are a result of the axial power distributions in the fuel rods. Thus, even if fuel melting occurred it would be confined to the center of the fuel pellets at the axial location of maximum power and would not interact with the cladding directly. The main fuel performance concern is the increased PCMI due to the increased volume of the small core of fuel that transforms from solid to liquid.

Thermal expansion

Thermal expansion of a material occurs because the bond length between atoms changes with temperature—increasing as the temperature increases. Because thermal expansion is assumed to be instantaneous relative to the fuel rod thermal time constant and transients are limiting at burnups where the pellet and cladding are in contact, the increase in pellet temperature results in a simultaneous increase in pellet diameter that must be accommodated by straining the cladding.

Fission gas swelling

Fission gas swelling during a transient event is considered secondary to fuel pellet thermal expansion. It is a secondary expansion mechanism because it isn't active at lower burnups and thus, is only a concern at higher burnups where the transient events are less limiting. Fission gas swelling has only recently been considered in fuel performance modeling.

The process of fission gas swelling in a transient is as follows. During a transient the temperatures in the pellet can increase to near the thermal limits of the fuel (i.e., the melt temperature). At temperatures near the melting point, the fuel is softened and deforms either by time-independent plastic deformation or by time-dependent creep deformation. The result is fission gas bubbles expand during the transient as much as the resistance of the cladding allows. The effect is for fission gas swelling to cause some increase in cladding strain in addition to that caused by thermal expansion of the pellet.

PCMI failure

The concept of pellet cladding mechanical interaction or PCMI was introduced in section “Interactions between the pellet and cladding” for normal operation. As discussed there, PCMI isn't active until there is gap closure between the pellet and the cladding ($\sim 25\text{--}30$ GWd/MTU at normal operating powers). During steady-state operation, the pellet increases in diameter from swelling and thermal expansion while the cladding creeps down because the differential pressure across the cladding causes irradiation creep. In an anticipated transient, the power increase causes an increase in fuel temperature, which causes the pellet diameter to expand. If there is still a gap between the pellet and the cladding in steady state, this temperature-induced expansion due to the anticipated transient will eventually close it and initiate PCMI. If the gap has already been closed during steady-state operation, the thermal expansion of the pellet in the anticipated transient causes the cladding to strain accordingly. The strain rates in the cladding during an anticipated transient are $> 10^{-4}/\text{s}$, meaning the deformation is time-independent plasticity. Thus, failure by PCMI is predicted to occur when the predicted strain in the cladding reaches a strain limit; 1% being the most common limit used for licensing assessments.

Design-basis accident performance

Anticipated transient events are events that might happen once in the lifetime of a plant, while DBAs are not expected to occur but could have a significant consequence if they did occur. Because of the potential severe consequences, these events are considered in the design of a reactor and the licensing of a core design to ensure such an event would not impact the health and safety of the plant operators or the public.

There are two specific types of design-basis accidents that are accounted for explicitly in licensing of a fuel assembly or an operating plan for a nuclear power plant. The first is the LOCA. This event is postulated as a removal of a section of large pipe (the so-called “double-end break”) causing the loss of coolant at a higher rate than can be replaced by the coolant make-up system. The accident at the Three-Mile Island plant in the United States, which caused the core to melt, was a LOCA-like event ([Skillman and Rempe, 2021](#)). The second is the RIA. The limiting RIA occurs when a control rod is suddenly removed from a reactor at zero power. In this accident event, prompt criticality occurs over milliseconds in a local region of the core, potentially shattering fuel rods and creating a pressure pulse that, if unaccounted for, can damage the reactor internals or pressure vessel. The SL-1 accident in the early 1960s, which killed three US Army soldiers, was an RIA event.

These events are addressed in reactor and core design in accordance with regulatory requirements to ensure core coolability is maintained and off-site dose is acceptable. Fuel failures may occur but must be accounted for in licensing analyses. However, licensing analyses are often performed to show fuel failures do not occur, to ensure there is significant margin against harmful radio-nuclide release. The following sections provide a description of the fuel performance phenomena that are expected in the LOCA and RIA events and considered in analyses.

LOCA

The time-temperature history for the cladding in a LOCA event is illustrated in Fig. 7. The first thing that happens in a LOCA is that the reactor pressure drops, which changes the coolant environment from water in the PWR and boiling film in the BWR to a steam environment resulting in less effective heat transfer between the cladding and coolant. The reactor then scrams (that is, automatic insertion of control rods shuts down the reactor). When the reactor power decreases, the temperature in the fuel follows. After about 10–20 s, the less effective heat transfer at the cladding surface is overwhelmed by the decay heat in the fuel causing the fuel temperatures to again increase. The rate of temperature increase in each rod will depend on the extent of the depressurization and the rod power prior to the event—with rods operating at higher power having more decay heat. The effect is that the cladding temperature increases well above its normal operating temperature while the peak temperature in the pellet will remain below normal operating conditions (except for in an accident severe enough to result in core melting). Therefore, the performance phenomena of interest in a LOCA event are related to how the cladding responds to the fission gas pressure and temperature from the interior of the rod (fuel rod ballooning and burst) and the low-pressure steam on the exterior of the rod (high temperature oxidation). In addition, for fuel at high burnup there is the concern of potential fuel fragmentation and relocation, which could result in fuel expulsion if burst occurs. After coolant has been added back into the reactor vessel, the temperatures start to decrease. Eventually, the cooling environment transitions back from steam to a boiling condition and the temperature drops dramatically, quenching the fuel. The limitations on high-temperature oxidation ensure the cladding maintains ductility to withstand the thermal stresses that occur during this quenching phase of a LOCA—avoiding potential breakage of the fuel rod into pieces and loss of rod geometry.

Performance phenomena in a LOCA

Fuel rod ballooning and burst

As the temperature of the cladding increases above the operating temperature, the lattice defects that caused irradiation hardening start to anneal out. That is, the dislocation loops created during irradiation “dissolve.” As the cladding anneals, the mechanical properties revert to those of the unirradiated condition. Yield strength and creep resistance decrease while ductility increases. The increasing temperature also causes the internal pressure in the fuel rods to increase. The result of these changes is that the cladding diameter increases at strain-rates more consistent with plastic deformation rather than creep ($> 10^{-4}/s$). Because of variations in the temperature, cladding thickness and axial burnup in the rods, there will likely be a local area where the cladding diameter increases at a higher rate than other regions. This results in a region of cladding ballooning. Then, like in a tensile test, the cladding will burst when the ultimate tensile strength is reached. After the cladding bursts, the deformation of the cladding stops at all elevations because the internal pressure driving the deformation is released.

Fig. 7 Representation of the cladding temperature as a function of time in a LOCA event; the heat-up rate, maximum temperature, and time will all depend on the actual event and the operating power of the rods prior to the event.

Fuel fragmentation and relocation

It is expected that during normal operation the fuel pellets are cracked into wedge-like pieces as illustrated in Fig. 4A. In addition, when fuel cracking occurs during the initial power rise, cracked fuel can relocate to fill the gap between the fuel pellet and cladding (relocation). Fuel fragmentation and relocation during the LOCA are extensions of these phenomena.

When the cladding diameter increases during a LOCA, a gap between the fuel and the cladding is created. This decreases the constraint on the fuel, decreasing friction between the fuel fragments and allowing potential relocation. Initially that relocation would be limited to the gap—meaning relocation occurs in the radial direction (similar to what might happen during the initial rise to power). When the size of the gap becomes larger than the size the fuel fragments, relocation can occur axially within the gap. This axial relocation is of greater concern than radial relocation because it can increase UO_2 mass at a given elevation—changing the neutronic characteristics of that location in the core. The concern is especially relevant where ballooning occurs because of the significant increase in gap size that fuel can occupy.

While axial relocation is a concern, it doesn't pose a significant safety hazard. The more significant concern is the potential expulsion of fuel into the coolant upon cladding burst, which could result in relocation of the fuel throughout the reactor system. The size of the fuel fragments relative to the size of the burst failure is an important factor when considering potential expulsion. It is now known that at high burnup, there is a post-LOCA fuel fragmentation mechanism that appears to be driven by fission gas release rather than thermal stresses, which drive fuel fragmentation under normal conditions. The regions of high-burnup structure (HBS) discussed in section “Fission gas release” are particularly susceptible to this mechanism, and could result in a high-energy expulsion of powder-size fragments through the burst cladding opening. In addition, there is some indication that this fuel fragmentation phenomenon may be triggered by the decrease in constraint of the fuel when the rod internal pressure drops with clad burst, which allows the full force of the fission gas pressure to act on the internal ligaments between fission gas bubbles. The consideration of this new fuel fragmentation mechanism has been the topic of potential new regulatory requirements for high burnup fuel.

High temperature oxidation

At the highest temperatures in the LOCA, high temperature oxidation is a concern. The potential for oxidation is limited by fuel design and core design. Fundamentally, high temperature oxidation and corrosion are the same phenomenon; the chemical reaction, $\text{Zr} + 2\text{H}_2\text{O} \leftrightarrow \text{ZrO}_2 + 2\text{H}_2$, is the same in both cases. The difference is the gaseous phase of the high-temperature H_2O in a LOCA oxidizes cladding at a much higher rate than does the liquid H_2O phase at normal operating temperatures; in other words, the oxidation rate in a LOCA is significantly higher than in normal operation.

High temperature oxidation can impact the performance of the cladding in two ways. First as oxidation occurs cladding is consumed. Effectively, the load-bearing thickness of the cladding is decreased as oxidation occurs. Given the difference in density between ZrO_2 and Zr metal alloys, the cladding thickness decreases 63% of the oxide thickness. That is, if the oxide thickness is 10.0 μm , 6.3 μm of metal was consumed. Second, because of the affinity of zirconium for oxygen, significant amounts of oxygen are absorbed into the metal lattice below the oxide film. Oxygen strengthens and embrittles zirconium alloys and thus can significantly decrease ductility. After burst occurs, high temperature oxidation on both the outside and inside surfaces of the cladding are considered.

To minimize the change in ductility, the specific performance metric often used by regulators is the percentage of the total cladding thickness consumed into the oxide film and the oxygen embrittled zone (termed the Equivalent Cladding Reacted, or ECR). Traditionally the ECR is calculated for a postulated LOCA based on correlations of steam oxidation data like Baker-Just (Baker and Just, 1962) and Cathcart-Pawel (Cathcart et al., 1977) and compared to regulatory limit like 17% ECR, which has been traditionally used in the United States. The expectation is that, by maintaining the calculated ECR to less than the regulatory limit, ductility in the cladding is maintained to withstand the thermal stresses that occur during the quenching stage, avoiding fuel rod fracture and rearrangement. Oxygen embrittlement is implicitly addressed by the ECR limit.

RIA

The RIA is a very short event (less than 100 ms) and occurs when a single control rod is quickly removed from a reactor core at zero power. In a PWR, the control rod is ejected when the drive mechanism at the top of the reactor vessel malfunctions and pulls the rod out or allows vessel pressure to push the rod out. In a BWR, the control rod is envisioned to become stuck in the core, subsequently disengage from the drive mechanism at the bottom of the reactor vessel and then later releases, dropping downward out of the core. In both cases the removal of the control rod causes a local prompt criticality event that is terminated by the Doppler reactivity feedback phenomenon. The control rod is then reinserted by a scram. The associated change in fuel enthalpy for both the PWR and BWR RIA events are provided in Table 1 (NEA, 2010) with the range in event times, and a representation of the fuel and cladding temperatures evolution is provided in Fig. 8 (USNRC, 2015).

The response of the fuel rod in an RIA has similarities to both the anticipated transient and the LOCA but over a much shorter time period. The power pulse causes the fuel temperature to increase rapidly. Like the anticipated transient there is a power increase with a subsequent increase in fuel temperature that results in PCMI. Like the LOCA, the local coolant environment changes to steam (a less effective heat transfer condition than pressurized water in a PWR or boiling film in a BWR), which subsequently causes the cladding temperature to rise with the fuel temperature. But because the coolant is never lost and reactivity feedback mechanisms terminate the power excursion, the event ends quickly, and the temperatures start to decrease. Thus, when considering potential failure mechanisms in an RIA, PCMI is possible as the fuel temperature rises and cladding burst is possible when the cladding is at the maximum temperature and the fuel temperature is decreasing.

Table 1 Estimated pulse widths and change in fuel enthalpies.

Reactor accident scenario	Pulse width (ms)	Maximum change in fuel enthalpy (J/gUO ₂)
PWR, rod ejection accident at hot zero power	25–65	80–250
BWR, rod drop accident at cold zero power	45–75	130–450

Modified from Nuclear Energy Agency (2010) Nuclear fuel behavior under reactivity initiated accident conditions, NEA-6847. OECD.

Fig. 8 Representation of the power change in a rod during an RIA and the subsequent impact on fuel and cladding temperature. Modified from US Nuclear Regulatory Commission (2015) Technical and regulatory basis for the reactivity-initiated accident acceptance criteria and guidance. Revision 1, NRC Memorandum, March 16, 2015, ML14188C423.

While the RIA could be analyzed considering the fuel performance phenomena explicitly, the regulatory requirements are universally based on empirical fuel rod test data that are used to define limits based on the applied fuel enthalpy. However, regulators have considered different fuel performance failure mechanisms by defining different fuel enthalpy limits for PCMI failure and for cladding burst. These limits are used analytically to show that failure doesn't occur or to quantify how many failures do occur for subsequent dose calculations, which is ultimately the concern in DBAs.

Fuel performance analyses

The thermal-mechanical response of fuel rods in normal operating and accident conditions is complex. The transfer of heat from the fuel rod to the coolant involves the heat generation within the pellet by nuclear fission, the transfer of that heat through the pellet, across the pellet-cladding gap, through the zirconium based cladding and then from the cladding outer surface to the coolant. Modeling this process over the entire lifetime of the fuel rod must account for material property changes in the pellet and cladding, geometry changes due to gap changes, and pellet diameter changes due to thermal expansion, densification and swelling. The heat transfer process is especially complicated by the reduction of pellet thermal conductivity and the evolution of gap conductance with burnup.

To predict the thermal-mechanical response of fuel rods, fuel vendors and regulatory agencies developed fuel performance models and codes that address the performance mechanisms noted above. These codes generally include a mechanics response module and a thermal response module. The mechanics model is often based upon the finite element method and the thermal model is generally based upon either the finite element or finite difference method. These codes generally address both steady-state and transient (AOO) response.

The vendor codes are used to assure safe operation by confirming compliance with licensing requirements as specified by the SAFDLs (e.g., the US NRC SRP 4.2) and to assure reliable and economic operation. The regulatory codes are used by regulatory agencies such as the US Nuclear Regulatory Commission to independently confirm vendor analyses and safety conclusions. For these reasons, codes are extensively qualified by (1) material properties tests on unirradiated and irradiated specimens and (2) integral on-line and post-irradiation examination (PIE) fuel performance data, including measured fission gas release.

After thermal-mechanical codes have been qualified and approved by regulators, vendors will use them to define steady-state operating limits with constraints on overpowers to account for anticipated transients. The steady-state operating limits are usually

expressed as power versus burnup or power versus time, and overpower limits are generally expressed in terms of percent overpower relative to the steady-state operating limit. Some vendors use a single overpower limit to protect against temperature and strain violations, while others specify both a thermal overpower limit to protect against temperature violations and a mechanical overpower limit to protect against cladding strain violations.

As discussed in section “**Design-basis accident performance**,” fuel rods are designed to meet different requirements during DBAs. The RIA is a fast energy deposition event that can be analyzed using a suitably-equipped thermal-mechanical code, but is often conservatively analyzed as an adiabatic event without a detailed prediction of the thermal-mechanical phenomenon described herein. Rather the maximum fuel enthalpy of the event is predicted using approved nuclear core/plant models and compared to the empirically based regulatory limits.

The LOCA is slow relative to the RIA and most anticipated transients, and the concerns are different. During the LOCA event, fuel rod internal pressure increases due to fission gas release and the cladding is subjected to high temperature due to limited heat transfer from the cladding outer diameter to the steam environment. The major concerns are cladding ballooning and possible perforation. Most thermal-mechanical codes are not capable of predicting large cladding deformation response that are typical of ballooning or do not have fission gas release models that are valid for the fuel annealing conditions in a LOCA. Therefore, LOCA analyses are generally performed with codes that predict the plant responses of such events. The event conditions are used as inputs to the high-temperature oxidation correlations that predict ECR, which is then compared to a regulator limit, or the event conditions are compared to empirically based cladding burst limits.

Like the thermal-mechanical analysis of steady-state and anticipated transient conditions, the intent of plant-based RIA and LOCA analyses is to confirm the licensing requirements for these design basis accidents are satisfied.

Summary

The performance requirements for LWR nuclear fuel are challenging because the LWR operating environment is challenging. The fuel must withstand elevated operating temperatures, a highly corrosive environment, the damaging effects of uranium fission and neutron irradiation, and stresses from both external and internal pressure and PCMI. This necessitates understanding the performance phenomena of both the UO_2 fuel pellet and the zirconium alloy cladding under all operating, transient and accident conditions so that performance models can be utilized to show compliance to regulatory requirements. To learn more about the details of the issues discussed herein, a list of further reading has been provided.

Introduction

Fast-spectrum nuclear reactors (or “fast reactors”) are distinguished from thermal-spectrum reactors by their lack of neutron moderating materials, enabling high-energy neutrons sustain the fission chain reaction. Because fissions are less likely to occur at higher neutron energies, fast reactors require higher neutron populations than thermal spectrum reactors in order to achieve the same core power density. The abundance of high-energy neutrons is useful for breeding fissile isotopes from fertile isotopes relative to the fission rate and for splitting minor actinides into shorter-lived isotopes to greatly reduce the radiotoxicity of spent nuclear fuel. However, this high quantity of higher-energy neutrons, however, also increases neutron-induced atom displacement damage to structural materials. Crucial components such as reactor pressure vessels can be designed to reside far enough from the core to reduce incident neutron intensity and, thus, fast neutron damage, but some structural materials (e.g., cladding and coolant ducts) must reside very near the fuel itself and thus be able to survive the challenges of fast neutron damage and other harsh environmental conditions.

Fast reactor physics favoring the breeding of fissile isotopes have historically been emphasized as a major advantage point—especially at a time when uranium-rich natural resources were not so well-known—and they remain of interest in countries with fewer uranium resources relative to population demands. The physics conducive to minor actinide splitting, as well as compatibility with plutonium fission, continue to be notable for creating more advantageous fuel cycles and disposition strategies (Wigeland et al., 2014).

While several different types of fast reactor designs are likely viable, most experience to date has been gained via cores cooled by liquid sodium (see Heidet, 2021; Hejzlar, 2021). The remainder of this article focuses primarily on the irradiation performance of the most common fuel systems used in sodium-cooled fast reactors (SFRs) as well as modern reactor designs. Other fast reactor systems are discussed elsewhere: lead-cooled (Alemberti, 2021), gas-cooled (Halata, 2021), and molten-salt-cooled (Krepel and Kramer, 2021). These fuels include oxide fuels—(U,Pu)O₂ and UO₂—and metallic alloy fuels—U-Zr and U-Pu-Zr. In this article, light water reactor (LWR) fuel technology is used as a known point of reference. For more information on fast reactor technology see (Waltar et al., 2012).

Fuel design

Overview

Fast reactor fuel technology is dominated by relatively simple designs consisting of a cylindrical nuclear fuel column encapsulated in a cladding tube hermetically sealed at both ends. Though appearing simple, this fuel design was optimized over decades of R&D, and it contains a host of subtle features enabling reliable long-term performance in environments that are extremely challenging for material performance. For most SFR designs, the residence time of fuel in operation is 1–3 years though the fuel in some designs is proposed to last decades, even the entire lifetime of a reactor plant. Core reactivity management strategies involving long irradiation lifetimes and high fuel burnup are achievable due to the higher initial fissile loading and fissile isotope breeding in fast reactor fuel systems. Thanks to the efficient heat removal capability of liquid metal systems employed in fast reactors, a high-power density is also achievable compared to water-cooled systems. Table 1 offers a comparison of typical SFR and LWR performance conditions, for perspective on the dramatic contrast in the fuel performance demands for each.

Table 1 Representative LWR and SFR service conditions illustrating performance comparisons relevant to fuel considerations.

	Core power density (W/cm ³)	Peak power density (W/cm ³)	Peak linear heat generation rate (W/cm)	Peak heat flux (W/cm ²)	Peak rod average burnup (operation, demonstrated) (GWd/t)	Neutron flux (n/cm ²)	Typical cladding irradiation damage (dpa)	Coolant temperature (K)
LWR	100	400	250	80	62, 100	10 ¹⁴	10–15	573
SFR	300	2000	450	260	90, 200	10 ¹⁶	100–150	873

Design limits

The overarching goals of fuel design are to achieve economic fuel cycle performance and reliable operation in service, and to ensure that offsite dose limits for all reactor design-basis conditions (including postulated accidents) are minimized and maintained within known margins. More practically, fuel designs are evaluated to identify every potential degradation mechanism and quantify the failure thresholds for relevant operating parameters. Predictive fuel performance models play a crucial role in this effort as the ultimate product of R&D programs for demonstrating acceptable fuel behavior has an adequate margin to fuel failure (see Section “**Fuel performance modeling**”). (Note that fuel failure includes not only fuel cladding breach but also other conditions such as unacceptable fuel rod or fuel assembly deformation.)

To illustrate how design limits for fuel might be applied it is helpful consider the specified acceptable fuel design limits (SAFDLs) established by the U.S. Nuclear Regulatory Commission (NRC). Adherence to these SAFDLs ensures acceptable performance of the fuel under normal operational and unanticipated transient conditions. For LWR fuel systems, the NRC established fuel damage criteria in its Standard Review Plan (NUREG-0800), Section “**Mid-to-high burnup evolution (<10 at% burnup)**”. The primary purpose of these criteria is to ensure that the fuel system is:

- 1) Not damaged as a result of normal operations and anticipated operational occurrences (e.g., any transient power or coolant condition)
- 2) Never damaged to the point that control rod insertion is prevented when needed
- 3) Conservatively assessed in regard to the number of failed fuel rods in accidents
- 4) Always maintained coolable (“coolability”).

For fast reactor fuels, no such explicit SAFDLs exist under a unified standard such as that developed by NRC for LWR fuels. However, many SFRs have been built and operated using defined limits that serve similar purposes. Recent work has proposed revisions for specific application to SFR fuels (Belles et al., 2017). For a better understanding of fuel performance under the most relevant conditions, note the following four defining criteria, which are common to the oxide and metallic fuel systems described in this article.

1. Limit cladding strain/stress—The cladding is the first barrier against fission product release and criteria are imposed to ensure cladding integrity. Frequently, such criteria are associated with concerns related to fuel-cladding mechanical interaction (FCMI) and over-pressurization due to fission gas release.
2. Maintain an adequate temperature margin to fuel melting—For various reasons, this criterion is common to all fuel systems, as explained in greater detail in coming sections. In short, ensuring an adequate temperature margin to fuel melting has been sufficient to avoid quantifying the uncertainties in molten fuel behavior and the resulting consequences.
3. Limit fuel-cladding chemical interaction (FCCI)—FCCI can threaten the cladding, degrading its structural integrity by effectively reducing the load-bearing thickness of the cladding wall. (This is also referred as cladding “thinning” or “wastage.”)
4. For certain accident conditions, post-failure behavior must preclude loss of coolability. This encompasses a wide range of considerations—primarily, maintaining fuel and core component geometries within the expected thresholds.

It is helpful to consider the complexity of fuel performance in the context of these criteria. One significant implication is that fuel performance must be understood in order to ensure cladding integrity while efficiently transferring heat to the reactor coolant. Therefore, the complexity of fuel performance is sometimes simplified to interpret its impact on cladding performance as a priority.

Common SFR fuel designs and key properties

Background

Several fuel systems and designs have been considered, tested, and developed to varying levels of maturity. Four primary fuel systems have been developed to significant maturity: oxides, metal alloys, carbides, and nitrides (Crawford et al., 2007; Delage et al., 2013). However, international experience is dominated by the use of oxide and metallic fuels, thus they are the focus of the detailed performance discussion in this article.

Mechanical design and function

The existing knowledgebase for fast reactor fuels is dominated by fuel designs in which a reactor core is composed of many assemblies (or “subassemblies” when related to the core assembly) of fuel pin (or rod) bundles. Frequently these fuel pin bundles are shrouded within a duct that has fittings attached to each end for mechanical interfaces and coolant inlet/outlet paths. Within the duct, the pins are arrayed on a hexagonal pitch and typically spaced apart using wires wrapped helically around the cladding of each pin. The vast majority of fuel designs have featured relatively similar design specifications.

As with traditional LWR fuels, each fuel pin is composed of a cladding tube that comprises an outer structural shell, along with an internal volume filled with the fissile fuel. The cladding and fuel are cylindrically shaped. In ceramic designs, the fuel typically takes the form of a stack of individual pellets (like those in LWR fuel rods), while metallic fuel designs generally employ monolithic columns or “slugs.” The required number of slugs is dependent on the fuel column length and fabrication method limits on slug length, attempting to minimize the number of slugs. Fuel smeared density (the areal fraction of cladding’s internal cross-section that is comprised of fuel) is a crucial parameter for any fuel type to achieve acceptable performance at high burnups and under transient conditions. The free volume within the fuel pin (i.e., a plenum located above or below the fuel column, the annular gap between the

fuel and the cladding, and in some designs a central hole in the fuel) is used to accommodate fuel thermal expansion, irradiation-induced swelling, and swelling due to fission gases and solid fission products. Metallic fuel designs include a sodium fill to provide good thermal transport from the fuel to the cladding. Annular fuel pellets (containing a central axial hole) are now common in oxide fuel to provide the desired smeared density while also producing benefits in terms of accommodating FCMI and improving transient behaviors (including providing a wider margin to fuel melting). Annular geometries for metallic fuel have received growing interest as a design solution that allows for eliminating the sodium from the pin while still maintaining good heat transfer between the fuel and cladding. Despite its performance-enhancing design features in metallic fuels, the in-pin sodium requires unfavorable disposal considerations when used in a once-through fuel cycle (e.g., U.S. regulations restrict the amount of reactive metal that can be disposed of with radioactive material in a geologic repository) (Fig. 1).

In some cases, fast reactor fuels include high concentrations of transuranic actinides (recycled from LWR or fast reactor fuel). These are typically referred to as minor actinide (MA)-bearing fuels, and their express purpose is to leverage the fast neutron spectrum in order to transmute the long-lived MAs into isotopes with significantly shorter half-lives (by a factor of approximately 300×). For a detailed overview of MAs' impact on fuel performance, see OECD-NEA, 2014.

Fuel types and design

Metallic and ceramic fuels have both been proven viable by in-reactor experiments and use in prototype plants. In both metallic and ceramic designs, the addition of plutonium is known to create some performance differences. Besides the in-reactor performance of these fuel systems (including safety-related performance), other engineering tradeoffs exist in terms of fuel supply/fabrication and post-irradiation processing in recycle and disposition (Wigeland and Cahalan, 2009).

Mixed oxide (MOX) fuels (U,Pu)O₂ have become the dominant fuel used in fast reactors internationally, thanks to established fabrication techniques, demonstrated performance, and operational experience mostly established through the LWR industry in the 1950s and 1960s (Waltar et al., 2012). Despite some disadvantages (e.g., poor thermal conductivity and lower density), oxide fuels benefit from having no allotropic changes, a high melting point, and low swelling rates. A summary of MOX fuels' important performance-related properties is found in Table 2. Though fuel designs vary, typical fuel parameters include a low oxygen/metal (O/M) ratio to mitigate fuel chemical interaction with the cladding. Fuel smeared densities typically range from 80–90%, with lower smeared densities showing greater resilience at higher burnups and under transient conditions. To achieve the desired smeared density, common fuel designs include both solid and annular (central hole) fuel pellets, with the annular pellets showing notable improvement in FCMI behaviors, especially during transients. Fuel pin diameters have typically been around 1/2–2/3 those of LWR rods with fissile fuel columns ~1 m long. Over decades of development, the fuel pin plenum was enlarged to incorporate an increasingly large free volume for accommodating increased fission gas release at higher burnups. Table 3 presents an overview of representative fuel design parameters relevant to discussions in later sections.

For metallic SFR fuels, an irradiation database exists to support fuel licensing under performance limits comparable to those of oxide fuel (Walters et al., 2011). The important characteristics of metallic fuels are (1) relatively high thermal conductivity and material density, as shown in Table 2 (see Novascone (2021) for more information on metallic fuel properties); (2) relative insensitivity

Fig. 1 Simplified overview of fuel pin designs typically used for liquid metal cooled reactor designs.

Table 2 Important performance properties of MOX and metallic fuels.

	MOX (20% PuO ₂)	Metal (U-20Pu-10Zr)
Theoretical density at 293 K (g·cm ⁻³)	11.1	16.2
As-fabricated density at noted temperatures (g·cm ⁻³)	10.3 → 9.70 ^a	15.3 → 15.1 ^b
Melting temperature (K)	3050	1350
Thermal conductivity (W·m ⁻¹ ·K ⁻¹)	3.5 → 2	20 → 25
Specific heat capacity (J·kg ⁻¹ ·K ⁻¹)	300 → 450	170 → 150
Thermal expansion (10 ⁻⁵ ·K ⁻¹)	1.0 → 2.0	1.7 → 2
Young's Modulus (GPa)	225 → 150	60 → 10
Centerline temperature (K), homologous temperature (T/T _{melt}) at 40 kW/m	~2373, 0.8	~1073, 0.8

Where applicable, values given are for typical fuel temperature distributions during operation: the MOX fuel range is 873–2373 K; the metallic fuel range is 873–1073 K.

^a95% theoretical density.

^bDensity accompanying injection casting; recent fuel extrusion shows about 3.2% increased density (very near theoretical density).

Table 3 Representative fuel design parameters included for reference (Crawford et al., 2007; Waltar et al., 2012; Guerin., 2012).

	Mixed oxide	Metal
Nominal composition	(U,Pu)O ₂	(U-Pu-Zr)
%Pu	15–30	0–26
O/M ratio	1.95	n/a
Fuel density (% theoretical)	95	100
Fuel height (mm)	100	100
Fuel diameter (mm)	5–7	5–7
Central hole diameter (mm)	0–2	0–1.5
Cladding outer diameter (mm)	6–9	6–8
Smeared density (%)	80–85	75
Plenum/fuel volume ratio	1	1.5
Fuel-cladding annular gap fill	He	Na

to most design variables, (3) reprocessing and refabrication options that demonstrate superior security and economic benefits as compared to other fuel types, and (4) inherent attributes that reduce the complexity of the core design and control systems. Metallic fuel presents complex allotropic evolution dependent on alloy composition and temperature, which becomes a dominant theme in its performance. The modern reference alloys are U-Zr and U-Pu-Zr, with Zr concentrations of up to ~10 wt.% to improve chemical compatibility with steel cladding alloys, raise the fuel solidus temperature, and provide a workable fuel fabrication temperature. Typical fuel smeared densities are ~75%, virtually eliminating the fuel-swelling-induced failures seen in early metallic fuel designs with higher smeared densities. Fuel pin diameters are varied to optimize different performance parameters, but (as with MOX fuel) are roughly 1/2–2/3 the diameter of LWR rods with fissile fuel columns ~1 m long. As with oxide fuels, metallic fuel designs include a large plenum to reduce internal pressurization that accompanies the desired high fission gas release. Typical fuel performance properties and design parameters for both fuel types are given in Table 3.

Fuel assembly structural material performance

Most irradiation experience involving fast reactor fuel cladding, flow ducts, and other components that must reside in the reactor core during irradiation (i.e., wire wraps, pin end caps, axial reflector blocks, etc.) largely pertain to stainless-steel alloys (Fe-based alloys with Cr, Ni, and other metals). Compared to zirconium-based alloys (used in LWR plants because of their relatively lower neutron capture), stainless-steel alloys are more attractive for SFR applications because of their improved strength at high temperatures at which the abundant high-energy neutrons in fast reactors are less susceptible to parasitic neutron capture in the cladding. Due to their essential functions, much of the focus of alloy development has been on cladding tubes and the flow ducts surrounding the pin bundles. Cladding materials serve to retain fission products in the fuel pin, isolate fuel materials from the coolant, restrain fuel swelling, and retain fission gas pressure in a coolable geometry. The ducts serve to maintain the structural functions of the fuel

assemblies and establish a well-defined coolant flow path. Their stable geometric behavior is important for thermal hydraulic functions and to enable fuel removal, shuffling, and reinstallation. Conveniently, the primary corrosion and hydrogen pickup issues that drive LWR alloy development do not apply to stainless-steel alloys in sodium cooled plants. However, both the cladding and ducts are challenged beyond LWR conditions with higher temperatures and fast neutron damage rates. As with LWRs, fast reactor cladding is also challenged by chemical and mechanical interaction with the fuel material.

Apart from performance phenomena relevant to fuel-cladding interaction, (covered in the next section), the principal challenge for fast reactor structural materials is dimensional stability at high fast-neutron damage. A tremendous number of irradiations have been performed on conventional stainless-steel austenitic alloys 304 and 316, which show excessive swelling at irradiation doses of above 50 displacements per atom (dpa) (in solids, dpa is used to measure the irradiation effect on material properties). In stainless-steel alloys the fundamental issue of void swelling drives dimensional changes in which kinetic collision with fast neutrons displaces metal atoms from their crystallographic lattice. The process creates atom interstitials and vacancies (point defects), as well as dislocations in the atomic lattice. Most of these defects self-annihilate quickly at reactor temperatures, though some evolve and interact with one another. Swelling results from the preferential attraction of interstitials towards dislocations. Excess vacancies become supersaturated and coalesce, initiating void nucleation and growth at reactor operating temperatures (Chen, 2013). Alloy modifications such as titanium additions and cold working extend this incubation period in advanced austenitic alloys (e.g., D9, 15-15Ti, PNC 1520), making them viable for doses of up to around 160 dpa, depending on the specific alloy type and design details (Cheon et al., 2009). Due to these limitations austenitic alloys have not been preferred for applications intended to support very high-burnup fuels with cladding doses of 200 dpa and beyond.

More recent SFR cladding designs have employed ferritic/martensitic (F/M) stainless steels in lieu of austenitic alloys, thus decreasing the swelling behavior (especially at high doses), attributed to their bcc crystal structure and complicated defect-sink interactions (Chen, 2013). Various F/M alloys have been developed and tested in different SFRs worldwide including notable alloys HT9, EM12, DIN 1.4914, and PNC-FMS. These alloys exhibit behavior similar to that of austenitic alloys, but with markedly reduced steady-state swelling rates. F/M alloys have been irradiated up to 200 dpa and can, in principle, withstand even higher doses. Accordingly, F/M alloys are preferred over austenitic alloys when it comes to high-dose applications, but can be more challenging from a tube fabrication and welding standpoint. The most notable disadvantage of F/M alloys is their relatively low creep strength at above ~ 925 K. F/M alloys are a logical choice for high dose duct materials in modern SFR core designs, which typically experience temperatures below 925 K. Ongoing developments for other industries suggest that constituent modifications may yield F/M alloys with improved creep strength for nuclear application (of particular interest in regard to SFR fuel cladding), but these advanced alloys have yet to be extensively tested in neutron irradiation environments.

Advanced fast reactor plants designed to maximize economic power production through increased coolant temperatures and very high fuel burnups may be better served by other advanced cladding alloys. Among these, ferritic oxide dispersion strengthened (ODS) steels stand out as potentially offering both low swelling behavior and superb mechanical properties at high temperatures, likely enabling reliable cladding operation at up to 700 °C. Some irradiation data on ODS alloys exist, but a more robust irradiation performance database is needed to foster ODS cladding deployment in fast reactors. Since ODS alloys are also more difficult to fabricate via conventional methods, fuel assembly designs using ODS cladding will likely be well-served by using F/M alloys as materials for the duct, which operates at lower temperatures (Cheon et al., 2009). Finally, other advanced alloys have been proposed and are in development for SFR application, in an attempt to retain the high swelling resistance of F/M alloys while also affording improved high-temperature strength and creep resistance (Hoezler et al., 2020).

Fuel performance under normal and anticipated conditions

This section describes the known behaviors of both ceramic and metallic SFR fuels during sustained normal reactor operation from beginning of life to plant discharge. This mode is typically referred to as “steady-state operation,” though it includes deliberate transients such as startups, shutdowns, and power adjustment maneuvers as well as core power distribution shifts resulting from control element adjustments and the spatial effects of burnup/breeding evolutions. These expected operations can also include minor transients resulting from occasional equipment malfunctions and cladding breaches on a limited amount of fuel elements. Section “Fuel performance under off-normal conditions” covers off-normal conditions including cladding breaches and general transient behaviors. Many excellent works provide extensive and detailed summaries of the irradiation performance of SFR oxide fuels (Olander, 1976; Boltax, 1994; Guerin, 2012; Papin, 2012; Waltar et al., 2012; Crawford et al., 2007). For metallic fuels, similar detailed overviews may be found in (Hofman et al., 1997; Ogata, 2012; Chang, 2007; Seidel et al., 1986; Crawford et al., 2007). For uranium nitride and carbide, see (Manara et al., 2012; Sengupta et al., 2012).

Early life evolution

Fuel lifetime begins with the insertion of fresh fuel. Fuel fabrication is described in Porter and Crawford (2021) and Kato (2021) for metallic and oxide fuels, respectively. For oxide fuels, beginning-of-life irradiation behavior is marked by the rise to power achieving high centerline temperatures and steep temperature gradients in the fuel. In metallic fuels, early-life behavior is most notably affected by fission gas induced swelling, though significant thermally induced evolutions begin as well. Due to the fuel swelling, both fuels are expected to have some degree of interaction with the cladding, and thus fuel design incorporates optimized fuel

smeared densities specific to each composition. In either case, significant thermal/chemical/mechanical changes begin to take place during early life at full power.

Mixed oxide fuel (U,Pu)O₂

The first rise to full power for newly manufactured fuel pins marks the introduction of cooling and internal nuclear heating, creating significant temperature gradients across the radius of the fuel. In fresh fuel, peak power locations typically drive MOX fuel centerline temperatures to as high as 2500 K, contrasted by coolant temperatures of 800–900 K. The resulting temperature gradients in the fuel may exceed 600 K/mm. In brittle ceramics at low temperatures, the thermal stresses easily exceed the fracture strength of the oxide fuel, inducing radial cracks in the pellets as the hotter fuel center expands more than the periphery. After achieving full-power conditions, the fuel microstructure quickly begins to undergo dramatic changes—many occurring within hours—driven by the thermal extremes experienced by the fuel. Across the fuel radius, the initially uniform hypostoichiometric O/M ratio of the fuel becomes radially distributed with a minimum towards fuel center as oxygen redistributes down the temperature gradient in the fuel, impacting material properties (e.g., melting point, thermal conductivity, species diffusion coefficients, etc.). The fuel develops a well-known multilayered ring structure consisting of a central void region, a ring of columnar grains with radial orientation, a layer of equiaxed grain growth, and the as-fabricated microstructure (e.g., see [Olander \(1976\)](#)). [Fig. 2](#) illustrates these developing behaviors.

In the center region of the fuel where temperatures can exceed 2075 K, pores created during fabrication migrate up the temperature gradient to form a single central hole (or “void”) within hours of operation. This results in the creation or expansion of a central hole in the fuel, which also conveniently vacates what would otherwise be the peak temperature location. The mechanism of pore migration is thought to be fuel evaporation/condensation across the pore (due to the difference in fuel vapor pressure between the hot and cold sides of the lenticular pores) as well as the diffusion of the oxide surrounding the pores ([Olander, 1976](#)). This process develops near crystalline grains with higher density and thermal conductivity, healing cracks formed during the initial rise to power. In Pu-bearing fuel, the fuel vapor transport mechanism favors U constituents, such that the columnar grain region results in higher Pu content towards the fuel’s central region. In the middle radial region, classical high temperature grain growth occurs resulting in a region of larger equiaxed grains. At the colder fuel periphery, the microstructure remains largely in an as-fabricated state.

Though the cladding has a higher coefficient of thermal expansion than the fuel, the higher temperatures in the fuel cause a net reduction of the fuel-cladding gap. The gap is additionally reduced due to fuel cracking, which also causes “relocation” of the outer diameter of the fuel towards the cladding. Temperature and irradiation-enhanced creep in the fuel also begin contributing to radial expansion in the fuel.

Fig. 2 Schematic overview of the irradiation lifetime of MOX fuel.

Metallic fuel (U-Pu-Zr)

In contrast, metallic fuels exhibit much lower intrinsic porosity, higher thermal conductivity, and ductile mechanical behaviors early in life. Thus, metallic fuels do not exhibit such marked thermal gradients, thermomechanical cracking, or pore migration during the first rise to power. Peak fuel centerline temperatures may approach 1200 K, resulting in smaller peak temperature gradients in the fuel (up to 120 K/mm). As-fabricated metallic fuel “slugs” contain a relatively uniform distribution of alloy constituents throughout. At power, the alloy constituents begin to migrate under driving forces established by the local temperature and local fuel composition, resulting in a redistribution across the radius that directly aligns (and is visibly obvious in post-irradiation examination (see Fig. 3)) with the isotherms within the fuel. The rate of constituent migration remains largely unquantified though it has been observed in the early life of the fuel and is driven by the temperature distribution in the fuel. Zr tends to migrate towards the higher-temperature center of the fuel and towards the periphery, both of which are beneficial outcomes in terms of providing a high centerline solidus temperature and more FCCI-resistant Zr content near the cladding. Uranium moves in the opposite directions while the Pu in Pu-bearing fuels largely remains stationary. This redistribution of alloy constituents plays an important role in the behavior of the fuel, affecting properties in each region of the well-known two- or three-layered structure visible in Fig. 3. The redistribution is somewhat altered as the fuel cools down later in life at lower powers and the radial position of phase fields move. Fig. 4 illustrates the evolution of changes in a metallic fuel during service.

As irradiation proceeds, the growing number of fission gas bubbles is largely retained as nano bubbles in the fuel matrix; they then begin to coalesce into larger pores depending on local zonal properties. Elevated temperatures and atom vacancies formed from fission and fast neutron collisions accelerate the fuel's creep behavior in response to the internal fission gas pressure. These behaviors cause metallic fuels to swell significantly during early-life burnup accumulation. They also are the primary cause of degraded thermal conductivity in the fuel. This behavior continues until $\sim 2\text{--}3$ at.% burnup, when the $\sim 30\%$ volume increase allows pore interconnection to enable fission gas transport more freely into the rod's internal volume. As porosity interconnects, the sodium fill in the pin begins to migrate into the fuel, helping restore the thermal conductivity of the dense fuel matrix. Thus, the temperature evolution of the fuel also undergoes notable variations during this process (Bauer and Holland, 1995).

In the case of metallic fuels, FCCI is an important consideration at temperatures relevant to operation (even for early-life conditions). In this context, two primary mechanisms affect fuel performance: (1) lanthanide (fission products) attack of the cladding material causing wastage at the inner cladding wall and (2) Fe-U diffusion forming U-Fe compositions susceptible to eutectic liquefaction of the fuel and/or cladding (cladding being the obvious concern) at high temperatures. The former plays an increasing role with increasing burnup while the latter is typically of greater concern in regard to transient overtemperature conditions discussed later.

Mid-to-high burnup evolution (<10 at% burnup)

As irradiation proceeds, the fuel evolution increasingly relates to the creation and behavior of fission products along with continuation of the same early-life behaviors. Fission products come in the form of gaseous and solid constituents. These additions to the fuel system alter material properties and potentially introduce additional loading to the cladding (which undergoes its own evolution as overviewed in Section “Fuel assembly structural material performance”). After a few at% burnup, the fuel has expanded to contact the cladding and effectively create important fuel-cladding mechanical and chemical interactions. In most SFR designs, fuel burnups have achieved burnup limits of 5–10 at%, with deformation of structural materials (e.g., duct and cladding) being the most life-limiting factor, in regard to austenitic stainless-steel claddings.

For many nuclear fuels, fission gas behavior has crucial ramifications for fuel performance. Introduction of fission gas to the fuel pin increases the internal pressure loading on the cladding and degrades the thermal conductivity of the gas gap between the fuel and cladding. The solid fission product impurities in the fuel matrix degrade the thermal properties of the fuel reducing both the thermal conductivity and melting point. These new constituents also migrate within the fuel, driven by high temperatures and the gradients thereof to become a consideration for cladding chemical interaction and potential cladding breach.

Fig. 3 Examples of U-19Pu-10Zr irradiated to low and high burnup.

Fig. 4 Schematic overview of the irradiation lifetime of metallic fuel (U-Pu-Zr).

Mixed oxide fuel (U,Pu)O₂

As the fuel begins to accumulate burnup, the fuel structure undergoes continued cracking as a result of thermal cycling including additional circumferential cracks formed primarily while the fuel cools during shutdown periods. Cracks in the fuel can provide migration pathways to enhance diffusion rates in local regions (for example, via diffusion along crack surfaces, which is faster than diffusion via the bulk fuel material). In hypostoichiometric fuel, the fission process frees up oxygen atoms increasing O/M ratios, with the favorable effect of improving thermal properties. Solid fission products within the fuel matrix can alter the chemical properties of the fuel and may form metallic precipitates at higher burnups. Fission products that migrate down the temperature gradient eventually reach the fuel-cladding interface forming a layer called joint oxide gain (JOG). The JOG layer has a reduced thermal conductivity that is lower than that of the fuel but higher than that of fission gas. Furthermore, the JOG layer has relatively viscous properties, which allows it to serve as a mechanical buffer to the cladding and allows it to be extruded to other regions of the fuel in the event of fuel-cladding gap shrinkage. However, its fission product composition imposes deleterious corrosive effects on the cladding. Volatile constituents may exist in all phases across the radius and axis of the fuel and are likely to accumulate in colder regions of the fuel, producing a corrosive effect on the cladding. **Fig. 5** presents cross-section examples of MOX fuel irradiated at different power levels.

Fission gases formed within the fuel matrix precipitate into bubbles located within and between the grains of the fuel (termed intergranular and intragranular, respectively). The gas produced within the fuel induces local swelling and primarily diffuses through the fuel matrix to form bubbles, which may coalesce, interconnect, and continue migrating to cracks and the free volume, until finally venting to the fuel plenum. Fission gas release into the plenum increases with higher local temperature and fuel burnup. Fission gas release reaches nearly 100% at temperatures above ~1400 °C. At a certain burnup, the capacity to retain fission gases becomes saturated, and typical fission gas release reaches and sustains an 80–90% total release, at higher than even modest burnups. **Fig. 6** shows representative measured fission gas release for SFR MOX fuel as a function of pin average burnup. Fission and decay processes increase the total number of various smaller atoms in the system ultimately resulting in net positive fuel swelling. Relative to other fast reactor fuel types, the swelling rates are low and have proven constant over the explored burnups. The total swelling contribution is due to a combination of solid fission product and gaseous additions into the fuel.

Metallic fuel U-Pu-Zr

Coming from early-life burnup, metallic fuel undergoes a relatively dramatic thermal evolution as porosity in the fuel builds to the point of interconnection. The previously described temperature-driven characteristics governing material phase and compositional zones continue to play out with the addition of fission products, further complicating these behaviors. By 3–5 at.% burnup, zone formation is complete, with the aforementioned initial redistribution of alloy constituents also impacting local thermal properties.

Fig. 5 Examples of MOX irradiated at various power levels (~ 5 at%, 85% smeared density).

Fig. 6 Comparison of fission gas release for MOX and metallic fuels. Based on data from Hofman GL and Walters LC (1994) Metallic fast reactor fuels. R.W. Cahn, P. Haasen, E.J. Kramer (Eds.), *Materials Science and Technology, A Comprehensive Treatment*, vol. 10B, Frost BRT (ed.), Nuclear Technology\ VCH Verlagsgesellschaft mbH, p. 1.; Boltax A (1994) Mixed oxide fuel pin performance. In: Frost BRT (Ed.) *Nuclear Materials, Part II*, Cahn RW, Haasen P, Kramer EJ (Eds.), *Materials Science and Technology, A Comprehensive Treatment*, vol. 10B, Frost BRT (Ed.), Nuclear Technology\ VCH Verlagsgesellschaft mbH, p. 339; Guerin Y (2012) Fuel performance of fast spectrum oxide fuel. In: *Comprehensive Nuclear Materials*, vol. 2, pp. 547–578. Elsevier, ch. 2.21.

The thermal conductivity, reduced as a result of porosity growth, continues to recover as sodium backfills the growing network of connected pores. Solid fission products in the fuel matrix act as impurities and inclusions, ultimately decreasing thermal conductivity as they accumulate.

As with oxide fuels, fission products take various forms within metallic fuels. Such forms include gaseous, dissolved in the internal sodium, and in solution or precipitated within the fuel. Lanthanide fission products that collect in the fuel-cladding interface are an important performance consideration in terms of causing cladding wastage, which effectively weakens the cladding and forms low-melting-temperature eutectic compositions. This is exacerbated by elevated temperatures and burnup.

Fission gas release has been shown to be directly linked to the process of porosity interconnection and, thus, fuel swelling. After a few at.% burnup, the fuel typically reaches a near-constant fission gas release fraction of close to 80% (for smeared densities of $<75\%$), as illustrated in Fig. 6. Once again, the pin plenum is designed with a relatively large volume to accommodate this gas while maintaining manageable pressure within the cladding.

As fuel life progresses, a primary concern for fuel integrity is the combined impacts of reduced cladding strength due to FCCI and increased plenum pressure caused by fission gas release. Zonal microstructure evolution and gas porosity/sodium infiltration complicate accurate determinations of power to melt, due to uncertainties in the local thermal conductivity and solidus temperature of each radial zone. Precise quantification of these effects on thermal properties in metallic fuels is relatively nascent compared to the effort expended to understand oxide fuels.

Late life evolution (>10 at% burnup)

As fuel progresses to very high burnups, the increasing accumulation of fission products becomes an additional concern that must be accommodated volumetrically within the cladding, along with protecting the cladding from corrosive attack. Continued addition of “impurities” through fission products further degrades the thermal properties of the fuel. The impact of these changes is mitigated by decreased power generation and reduced fuel peak temperature due to the depletion of fissile isotopes in the fuel.

Mixed oxide fuel (U,Pu)O₂

As burnup becomes very high, dominant themes in fuel behavior resemble, from a thermomechanical standpoint, those found in earlier life, but with increasing impacts from accumulating fission products. Percent fission gas released remains relatively constant with continued increase of pressure in the pin plenum. Tellurium and cesium, which have migrated to the cladding, increase the internal corrosion of the cladding, and become increasingly problematic as time at temperature integrates with increasing burnup and with the continued addition of fission products. Cs migrates and accumulates in colder regions of the fuel (e.g., the ends of the fuels stack in low temperature regions and near UO₂ insulator pellets) where increased FCMI may occur and has been shown to manifest especially in very high burnup fuels (Guerin, 2012). Fuel designs must account for effects present at design-peak burnup in order to provide sufficient room for fuel swelling (including transients, as discussed later), depends on several factors, including cladding type. Typically, an initial smeared density of 80–85% is adequate to support experimentally validated burnups (around 20 at.% or more) and perform well under transient conditions.

Metallic fuel U-Pu-Zr

Progressing to very high burnups, solid fission products begin to fill the fuel's void space and will induce FCMI at some point, depending on the initial smeared density (for a burnup approaching 20 at.% with 75% smeared density). Still, experimentally measured cladding strain at 19 at.% has been accounted for by the effect of internal pin pressure alone. Regions of maximum FCCI tend to be in the upper portion of the fuel column, though not always at the region of highest fuel-cladding interface temperature (i.e., the top of the fuel column) for pins ~ 1 m in length. The peak FCCI location likely arises from high fission product availability via relatively high local fission rates, combined with a high interface temperature (Porter and Tsai, 2012). Fig. 3 includes an image of a high burnup metallic fuel specimen.

Fuel performance under off-normal conditions

The potential for fuel compaction via melting or dispersal scenarios is an important consideration in regard to SFR fuel in postulated accidents due to the resulting potential for reactivity insertion, power excursions, and propagation of damage to the core. Fuel-coolant compatibility is another important reactor design consideration. Of the primary fuels discussed herein, only oxide fuels have a meaningful chemical reaction with sodium coolant. The following sections provide an overview of important (and relevant) off-normal conditions such as operation with breached cladding, transient conditions such as overpower, loss of flow conditions, and severe accidents. Descriptions of hypothetical reactor conditions that could lead to these events is reactor-design-specific and thus beyond the scope of this paper.

Fuel performance with breached cladding

A variety of fuel defect types have been observed and their performance effects studied. Although fabrication and inspection methods are intended to minimize such defects, a core with thousands of pins is likely to contain defects that occasionally result in fuel pin failure. In this context, “fuel failure” refers to a breach of cladding hermeticity. For SFR oxide and metallic fuels, significant efforts were expended to understand the system response to breached cladding and its effects on operation. These studies focused on fission product release, fuel-sodium reaction behavior, and pin geometric stability.

When oxide fuel breaches, it contacts and reacts with the sodium coolant, forming reaction products that further degrade the fuel, sparking concerns over failure propagation by blocking coolant channels (loss of coolability). Experimental results revealed the volume increase within the fuel due to the formation of fuel-sodium compounds to be the primary mechanism of fuel pin degradation. The reaction product has lower thermal conductivity and decreases the fuel's O/M ratio, thus increasing fuel temperatures. The resulting effects of oxide fuel breach were successfully mitigated through proper fuel design (smeared density of <85%) and operation of the pins.

Metallic fuels are compatible with sodium (allowing for the internal sodium fill in the fuel pins). This compatibility leads to benign effects from metallic-fuel breaches and is an important feature regarding a variety of operational and accident conditions. Experiments involving the use of artificially defected cladding to instigate breach showed that the fuel can operate for extended periods (experimentally verified for up to 200 days) with minimal consequences, and they confirm the occurrence of negligible fuel-sodium reactions. Continued operation of breached pins all the way to the end of a reactor's operating cycle is manageable, the primary consideration being fission gas release into the primary coolant. A comparison of representative metallic and oxide fuel pins irradiated after cladding breach is shown in Fig. 7.

Transient conditions

Transient conditions of interest are classified as “operational transients.” These include reactor startup or shutdown, Anticipated Operational Occurrences, Design Basis Accidents (DBA), and Beyond Design Basis Accidents (BDBA). As implied by their names, categorization of these events is based on their probability of occurrence. Here, the events are listed in order of decreasing probability and reflect an increasing allowable uncertainty for quantified transient fuel behaviors. The resulting behavioral complexity also increases significantly under severe conditions, potentially leading to manifestations of material phase change and bulk

Fig. 7 Examples of artificially defected metallic and oxide SFR fuels run beyond cladding breach (Hofman and Walters, 1994, Strain et al., 1992, Chang, 2007).

relocations. As noted in Section “Design limits”, fuel design criteria directly apply to these events so behaviors must be well-enough understood to ensure compliance. The primary conditions discussed here include loss of flow (LOF) and transient overpower (TOP) conditions. For both these categories, “protected” and “unprotected” events (DBA and BDBA, respectively) are typically considered, based on whether active reactor shutdown systems are credited.

In each of these transient scenarios, the primary performance concern for the fuel relates to the effects of overheating conditions, which vary in timescales and severity for each event considered. Typical TOP events are relatively slow power ramps in the fuel induced by an unplanned control rod withdrawal and are considered local faults (impacts in the core localized near the control rod). In an LOF condition, fuel generates heat at a higher rate than the coolant can remove it (rates depend on the specific event classification), because cooling is reduced or lost. Fuel temperature gradients typically remain the same or decrease, but overall fuel and cladding temperatures increase. The dominant concern during a severe condition is progression to coolant overheating and localized coolant boiling (channel voiding), resulting in a positive reactivity insertion and subsequent fast overpower transient, thus leading to greater concern over additional reactivity insertions and overpower extremes. Still, even BDBA conditions in most modern SFR designs result in a rather benign fuel response. The following discussion briefly emphasizes the dominant phenomena during transient power-cooling mismatch conditions, which results in overheating (TOP and LOF) in the context of temperature rate effects, where protecting cladding integrity and understanding the margin to melting are dominant concerns.

Oxide fuel performance during transient conditions

A significant experimental database exists for oxide fuel transient performance (Papin, 2012). In a TOP event, cladding failure is primarily driven by the fuel cavity pressure loading overheated cladding. In this context, a “cavity” refers to a fuel region where temperatures may exceed the fuel solidus temperature, causing increased coalescence of high-temperature porosity. The resulting molten fuel-gas mixture forms a porous structure called “foam.” The lower-density fuel and high-temperature gases increase localized loading on the cladding, which could balloon depending on cladding temperature evolution and the kinetics of the internal accommodation of gaseous swelling and molten fuel expansion. Representative examples of transient behaviors in MOX fuel are given in Fig. 8.

In a pure LOF condition, the effects of fuel thermal evolution are generally less challenging are in an overpower event. Reduced cooling in LOF conditions causes the cladding surface temperature to rise while the power input decreases due to reactor shutdown and/or negative temperature reactivity feedback effects. Overheating within the fuel triggers phenomena similar to those described for TOP conditions. Stored energy (high temperatures) in the fuel can have a dominant effect on the margin to coolant boiling, resulting in positive void reactivity effects and added TOP conditions. Although, typically speaking, such conditions are highly improbable, LOF + TOP events with fast power ramp rates have been studied and show failure results from fuel thermal expansion and molten cavity pressure. Slower power ramp rates tend to show increased effects from gaseous swelling. Cladding breach during such an event is also influenced by the reduced strength or potential melting of the cladding due to increased temperature at the start of the power excursion, after LOF conditions have already progressed. In all cases, the increased cladding loading caused by the formation of a molten fuel cavity mixed with released fission gas is mitigated by lower smeared densities and in-pin fuel motion whenever a central hole is present in the fuel.

Metallic fuel performance during transient conditions

One of the most beneficial features of metallic fuels is that they possess inherent attributes that benefit core design and control systems by exhibiting helpful behaviors during off-normal conditions (Seidel et al., 1986; Chang, 2007; Wigeland and Cahalan, 2009; Sofu, 2017). Perhaps the most notable demonstration of the relationship between metallic fuel behavior and plant response under accident conditions was performed in EBR-II as part of the Inherent Safety Demonstration tests. A whole-plant, unprotected LOF initiated from full power was performed in the metallic-fuelled EBR-II facility (Planchon et al., 1987). In these demonstrations,

Fig. 8 Overview of observed MOX fuel responses to transient conditions showing fuel cross sections as well as the upper end of the fuel column, showing clear signs of fuel motion that occurred during the transient.

Fig. 9 Overview of the observed metallic fuel response to transient conditions.

the metallic fuel core exhibited no failures during the tests, nor afterwards during subsequent extended operations. In metallic fuels, reduced fuel temperatures yield less stored energy, thus diminishing Doppler reactivity effects and allowing LOF + TOP conditions to be more easily mitigated. The higher fuel density and harder spectrum core also require less excess reactivity to offset burnup (i.e., lower control rod worth), lessening the severity of accidental control-rod-induced TOP events.

More generally, the high thermal conductivity and high creep rate properties at relevant temperatures are key to good resilience of metallic fuels during transient off-normal conditions. In any transient scenario, cladding failure is caused by cladding rupture induced by the combined effects of cladding wastage from FCCI along with pin internal overpressure. Overpressurization effects are naturally exacerbated at increased fuel burnup from high accumulated fission gas release, whereas cladding eutectic penetration dominates the failure behavior in lower-burnup pins. Thus, fuel susceptibility to these two failure mechanisms is predictable from low to high burnups (Cohen et al., 1993).

The dominant FCCI behavior of concern in regard to off-normal performance is the eutectic interaction between Fe in the cladding and U in the fuel, with interdiffusion of each element between the fuel and the cladding. A eutectic temperature is found near 1000 K for high U-to-Fe concentrations. The net effect is greater induced melting in the fuel than within the cladding as illustrated in Fig. 9. Thus, the integrity of the cladding is not greatly imperilled until higher temperatures or long times at temperature are reached. Fuel liquefaction results in significant fission gas release and the coalescence of smaller gas bubbles from the matrix, inducing significant axial fuel swelling. Core-wide, this swelling serves to elongate the fuel column, leading to a beneficial, less-reactive condition. The relatively stable structure seen in Fig. 9 is sometimes called “foam.” As in normal operations, FCMI during transients shows a considerably less significant contribution (for smeared densities of <75%), due to significant fuel creep rates at elevated temperatures. Thus, the relatively ductile properties of the fuel mean that cladding loading is primarily driven by pin overpressure. Fig. 9 also includes a photomicrograph of fuel that underwent a fast transient resulting in melting of the fuel’s internal region, then extending towards the periphery. In fast power ramps, liquid phase eutectic penetration in the cladding becomes a dominant failure mechanism at high temperatures (>1350 K, a lower temperature eutectic for low U-to-Fe concentrations).

Post-failure behaviors in accident conditions

Fuel/core designs (and associated limits) for SFRs typically preclude the potential for conditions that lead to significant fuel failure, even during very low-probability transients. These conditions have been evaluated rather extensively for oxide (more) and metallic

fuels (less) in regard to the potentially significant consequences associated with them. Notable post-failure behaviors include a strong tendency for failure in the upper or top of the fuel column where cladding temperatures tend to be at a maximum both before and during a transient. The notable exception is for faster power ramps in oxide fuel systems, where peak temperatures may occur towards the core axial center, near maximum fuel power locations. In metallic fuels, peak temperatures more closely follow the coolant temperature in all cases (rising from the bottom to the top of the core). In metallic fuels, the top of the fuel column tends to also experience the highest FCCI effects caused by normal operation.

Transient experiments show that both metallic and oxide fuels expelled from the fuel column move upwards and out of the core towards regions with a lower neutron flux (i.e., into a less reactive state). Fuel-coolant compatibility plays a role in the potential formation of coolant blockages that reduce flow and may induce the failure of other nearby fuel pins (failure propagation and a threat to core coolability). Still, with large uncertainties in the evolution of extremely low-probability events and the resulting phenomena, the risk of recriticality after fuel dispersal has not been ruled out for oxide-fueled sodium fast reactor designs (Papin, 2012), while the metallic fuel system displays inherent characteristics (e.g., compatibility with sodium, low temperatures) more favorable for avoiding such concerns (Sofu, 2017; Tentner et al., 2019).

Fuel performance modeling

A nuclear fuel technology package includes the fuel design, knowledge of fuel performance and limits, and modeling tools to support development and evaluation. Fuel performance codes are typically based on finite-volume or finite-element methods for evaluating the thermo-chemical-mechanical behavior of the fuel—a truly multi-physics problem whose complexity benefits greatly from computational frameworks.

Fuel performance computer codes have been instrumental in the nuclear fuel R&D, commercialization, and licensing since the invention of computers. A fuel performance code essentially functions as a repository of integrated fuel performance knowledge used for predicting fuel performance for various purposes. Fuel developers use fuel performance codes to design and evaluate behaviors in new fuel designs and experiments intended to push the boundaries of current human understanding. Thus, this process relies on the incorporation of state-of-the-art models to minimize the level of extrapolation. One commercial or regulatory interest is to evaluate fuel performance in the context of the SAFDLs for a given fuel/reactor system. Developers and commercial industry also use the codes to verify that fuel performance is within nominal targeted operational limits, with the goal of maximizing performance and economic benefits.

Several fuel performance codes have been developed to address relevant performance criteria for SFR fuels and include some capability for application to other fuels and/or reactor types. These codes rely on an experimental database that supports model development in order to address material properties and relevant behaviors. The experimental database is also used to validate models ranging from simple property relationships to full integral system behaviors.

Behaviors described in this paper that are important to performance and safety have been sufficiently modeled to allow successful operation of many SFRs. Still, the development and refinement of models continues for complex phenomena such as fission gas migration and release, JOG formation and behavior in oxide fuels, and complex FCCI mechanisms in metallic fuels. In some cases, the evolution of the technology has led to adequate, but imperfect descriptions of material behaviors. For example, FCCI in metallic fuels has sufficient supporting experimental data over a variety of material types and burnups to validate semi-empirical models shown to conservatively predict the extent of FCCI in cladding. Yet, the opportunity exists to further develop understanding by expanding the current experimental database, along with developing improved models that reduce uncertainties and justify performance increases. This evolution in our understanding of fuel and increasing performance is seen in early SFRs (and especially LWRs) in which burnup and temperature were initially restricted to benign conditions—restrictions later relaxed as experience led to improved designs and reduced uncertainties.

Even with a rich historical knowledgebase, fast reactor fuel technology is making significant strides forward, thanks to the increasing availability of advanced experimental characterization and computational tools. As improved understanding of fuel performance translates into highly predictive capabilities, the true potential of the fuel technology may be unleashed to perform safely and with maximum utility.

Introduction

The tristructural isotropic (TRISO) coated particle fuel form enables the realization of high-temperature gas reactors (HTGRs) and their attractive attributes such as passive safety and high outlet temperatures up to 950 °C, which facilitate industrial process heat applications and high thermal efficiencies for power production. The TRISO fuel concept has evolved considerably from the first coated particle fuel concepts developed in the 1950s during the initiation of the DRAGON Project in the United Kingdom (Price, 2012; Demkowicz et al., 2019). The first designs focused on carbide fuel kernels coated with a single layer of dense carbon in

a carbonaceous monolithic fuel form. These early designs allowed fission product release and pyrocarbon fracture, but they established a starting point to improve on the early coated particle fuel designs. Improvements included adding another carbonaceous layer—termed the *bistructural isotropic (BISO)* (Goeddel, 1967; Jaye and Goeddel, 1968) or *buffer isotropic* (Kania et al., 2015) layer—to accommodate phenomena such as fuel kernel swelling, pyrocarbon dimensional changes, and fission gas pressure (Demkowicz et al., 2019). The decades that followed saw significant evolution of the coated particle fuel form for HTGR concepts, ultimately leading to adoption of the modern TRISO-coated particle fuel form which evolved to its current form in the late 1970s and early 1980s. Multiple comprehensive reviews of TRISO fuel design and development have been published over the decades of TRISO fuel and HTGR research, development, and demonstration (Demkowicz et al., 2019; Zhou and Tang, 2011; Verfondern et al., 2007; Petti et al., 2012; Stansfield, 1991; Kania et al., 2015). These reviews serve as an excellent background for the overview of HTGR fuel irradiation performance presented herein, which focuses on the mechanistic behavior of TRISO fuel.

Fuel configurations for HTGRs depend on reactor design. The most prominent fuel forms are spherical pebbles for pebble bed reactor designs and cylindrical compacts for prismatic reactor designs. While construction of each fuel form varies according to specific reactor requirements, most systems share common design features (see Helmreich and Hunn, 2021). Generically, the fuel form consists of modern TRISO fuel particles embedded in a matrix of natural and synthetic graphite flake and carbonized resin. The modern TRISO fuel particle consists of five primary components: the fuel kernel and successive layers of low-density carbon buffer, inner pyrolytic carbon (IPyC), silicon carbide (SiC), and outer pyrolytic carbon (OPyC). Each coating layer is deposited in succession using a fluidized bed chemical vapor deposition process (Sawa, 2012). Fig. 1 shows a cross section of a modern TRISO fuel particle (Hunn et al., 2015a).

Each component of the TRISO fuel design provides specific functionality during fabrication and/or operation. The fuel kernel provides fissionable material to produce heat and sustain reactivity in the core. The kernel also plays a key role in controlling internal gas pressure, as well as stabilization and retention of fission products and actinides during irradiation. The fuel kernel in modern TRISO fuel is UO_2 or a heterogeneous mixture of UO_2 and UC_x which is commonly referred to as “UCO.” The kernel’s enrichment level in modern fuel is typically low enriched uranium below 20% ^{235}U , depending on the intended application and reactor design. Some early efforts used highly enriched uranium, but a shift was made to low enriched uranium due to proliferation concerns (Verfondern et al., 2007). Over the course of the TRISO design history, many other kernel compositions have been explored and considered such as thorium- or plutonium-based kernel compositions, to provide different fuel cycle options for HTGRs (Verfondern et al., 2007; Besmann, 2010). The low-density carbon buffer layer serves as an effective fuel plenum. The buffer attenuates fission product recoils, and it provides excess volume to accommodate fission gas production, as well as space to accommodate fuel kernel swelling. The IPyC layer provides structural support and retains select gaseous fission products. The IPyC layer also protects the kernel from chlorine attack during fabrication. The SiC layer provides the primary structural support of the particle, resisting internal fission gas pressure and fuel swelling, and is a barrier to metallic fission products released from the kernel. The OPyC layer provides another “gas-tight” layer, and it protects the SiC layer when the TRISO fuel is being handled prior to compacting into its final fuel form. The OPyC layer also provides a surface for overcoating to facilitate particle compaction. Particles are then overcoated, pressed, and heat treated to create the final form of TRISO fuel particles in a matrix of graphite and carbonized resin.

The matrix material provides structural integrity, heat conduction, and neutron moderation. **Table 1** identifies the nominal kernel and layer dimensions and provides details of (1) the selected fuel form of the German reference fuel which has been adapted for multiple fuel development programs around the world (e.g., the HTR-PM in China and the PMBR in South Africa) and (2) the UCO-TRISO fuel produced in the United States through the Department of Energy Advanced Gas Reactor Fuel Qualification and Development Program (AGR Program) (Kania et al., 2013; Phillips et al., 2010).

Although each TRISO fuel component provides specific functionality as described in the preceding paragraph, post-irradiation examination has shown clearly that a key aspect to the holistic performance of TRISO fuel is the synergy between the components. For example, the functionality of the kernel to retain actinides and fission products is only effective when gas is retained by the outer coating layers. Particles whose coatings have defective or failed gas retention properties can exhibit substantive kernel degradation due to unrestrained reactions with the surrounding carbon, this behavior is especially evident after safety testing (Hunn et al., 2018a,b, 2019b). Another good example is the fact that, while the Buffer and IPyC layers in the BISO particle exhibit poor retention for many metallic species, in the TRISO particle the Buffer and IPyC layers act as a barrier to prevent high concentrations of actinides and fission products from contacting the SiC. Fracture of these inner two coatings has been observed to result in degradation of the SiC by localized high concentrations of species such as palladium and carbon monoxide (Minato et al., 1991; Hunn et al., 2016).

HTGR fuel performance has been established through decades of irradiation testing in demonstration and prototype reactors and materials test reactors (MTRs) (Petti et al., 2012). The HTGR fuel operational envelope varies for prismatic and pebble designs. **Table 2** shows relevant irradiation conditions for select irradiation programs targeting both prismatic and pebble reactor concepts. Generally, irradiations to support pebble bed designs have lower particle volume packing fractions with lower power densities, burnups, and temperatures, compared with prismatic designs. Comprehensive discussions of the irradiation conditions for TRISO fuel can be found in the literature (Petti et al., 2003, 2012; Kania et al., 2013; Demkowicz et al., 2019; IAEA, 1997).

Irradiation performance

A primary metric for fuel performance is the retention of fission products and actinides within the coated particle. Retention of fission products within the particles is of importance as the TRISO particles are a primary reactor component which define the functional containment for HTGRs and supports the potential for reactor co-location with industrial processes such as H₂ production, desalination, and process heat (INL, 2011). The pathway for release from the HTGR fuel form requires release from the kernel, coating layers, matrix material, and finally reactor components in the coolant flow path, with each component mitigating release depending on temperature, diffusion, and absorption properties. The release of fission products from intact fuel at design-basis operating conditions is inherently low relative to the release from particles with as-fabricated defects or particles which fail during service (Hunn et al., 2016). For that reason, a primary emphasis has been placed on reducing the initial defect fraction in as-fabricated particle fuel and ensuring that particle failure in service is controlled to limit the source term.

Kernel release

Several behavior models have been developed to predict the release of fission products from the kernel, and summaries are presented in IAEA-TECDOC-978 and by Powers and Wirth (IAEA, 1997; Powers and Wirth, 2010). The kernel is the first barrier to fission product release from the fuel form, governing release from particles with exposed kernel defects. The fractional release from the kernel, sometimes defined as *release to birth ratio* (R/B), of long-lived and stable fission products is presented in Eq. (1) (Nabielek, 1976). In general, the R/B is the fraction of a specific radioisotope that has been released from a component (kernel, particle, fuel element, etc.) relative to the total inventory that was produced in the component. The R/B from the kernel depends on the diffusivity of the fission product or fission gas in the UO₂ kernel. It is generally expressed as a function of the irradiation time, t (s), and reduced diffusion coefficient D' from Eq. (2), where D (m²/s) is the diffusion coefficient for the fission product species in the kernel and a (m) is the radius of the kernel. D' follows an Arrhenius relationship. Data supporting release from UCO kernels are limited since the effective diffusivity is not explicitly known. Therefore, UO₂ diffusion coefficients are usually used to predict release (Collin et al., 2015).

$$\frac{R}{B} = 1 - \frac{6}{D't} \sum_{n=1}^{\infty} \frac{1 - \exp(-n^2\pi^2 D't)}{n^4\pi^4} \quad (1)$$

Table 1 Nominal kernel and layer dimensions of modern reference TRISO particles for HTGR applications.

Org.	Kernel	Buffer	IPyC	SiC	OPyC	Fuel form
U.S. AGR (Phillips et al., 2010) ^a	UCO-425 μm	100 μm	40 μm	35 μm	40 μm	Compact

^dIncluded transient above listed temperature.

$$D' = \frac{D}{a^2} \quad (2)$$

For short-lived fission products, Nabielek's work discusses that the release reaches steady state (Nabielek, 1976) and is then dependent on the competition between diffusive release and radiological decay. The Booth model for a spherical element is generally used to determine the R/B of short-lived fission products from the kernel (Booth, 1957; IAEA, 1997). Eq. (3) shows the steady-state R/B dependence for short-lived radioisotopes, where λ is the half-life of the radioisotope of interest. In the Booth model, when the condition $\sqrt{\lambda/D'} \gg 1$ is satisfied, then conditions for steady state have been met and it is appropriate to apply Eq. (3) to determine R/B of short-lived fission products.

$$\frac{R}{B} = 3\sqrt{\frac{D'}{\lambda}} \quad (3)$$

Diffusion is not the sole mechanism for release from the kernel: recoil release from fission occurring near the outer radius of the kernel also contributes. Fission recoils are responsible for ~2–3% of fission product release from the kernel for typical TRISO kernel sizes. These fission product recoils generally deposit in the buffer and are free to diffuse through the system. Eq. (4) characterizes fission product recoil release from the kernel (Ogawa et al., 1985). A primary design variable impacting fission product recoil release is the ratio of the kernel's surface area to its volume. In Eq. (4), z is the recoil range in the kernel.

$$\frac{R}{B} = \frac{3z}{4a} \quad (4)$$

The kernel's retention of fission products is also influenced by its chemistry. In particular, the introduction of uranium carbide in the kernel reduces its ability to retain metallic fission products by reducing its oxygen potential. The lower oxygen potential limits the kernel's ability to form stable oxides (Homan et al., 1977). This was highlighted in a study of the irradiation of bare uranium carbide kernels, which showed near complete loss of ¹³⁷Cs, ¹²⁵Sb, and ⁹⁰Sr (Nabielek, 1976). Similarly, the second irradiation experiment from the U.S. AGR program, AGR-2, included compacts with both UO₂ and UCO kernels that were irradiated to similar conditions. Table 3 lists the compact average irradiation conditions from the AGR-2 irradiation (Collin, 2018). Destructive post-irradiation examination (PIE) by scanning electron microscopy (SEM) with energy dispersive x-ray spectroscopy (EDS) of UO₂ kernel particles from Capsule 3 showed primarily palladium in the IPyC and SiC layers. Comparatively, the UCO kernel particles from Capsule 5 showed not only palladium, but also a consistent presence of uranium co-located with the palladium, suggesting lower U retention relative to the UO₂ kernel. As would be expected for thermal diffusion-related migration, the higher temperature UCO kernel fuel particles (Capsule 2) showed a greater concentration and diversity of fission products and actinides released from the kernel than did lower temperature UCO kernel fuel particles (Gerczak et al., 2020a). The release of fission gases and noble metals such as silver and palladium is not expected to be strongly impacted by kernel chemistry, because they do not readily form an oxide. However, noble metal inclusions were observed in UO₂ kernels and not in UCO kernels. Similarly, a significant release of lanthanides was reported from carbide kernel fuel (e.g., UC_x) if there was insufficient oxygen (O/U ≤ 1.1) to stabilize the fission products as oxides (Tiegs, 1982).

Fission product release through TRISO layers

Most fission products are well retained in modern, high-quality TRISO particles. Historically, biologically relevant fission products such as cesium have been observed to be released, along with silver, from both UO₂ and UCO kernel fuel (IAEA, 1997). However, modern TRISO fuel from the AGR-1 irradiation experiment has shown excellent retention of cesium, with a capsule average R/B < 3 × 10⁻⁶ for ~49,500 particles per capsule, which is much less than a single particle's inventory (~2 × 10⁻⁴) (Demkowicz et al., 2015). The U.S. AGR program has explored TRISO fuel irradiation behavior over a broad range in conditions. Irradiation temperature has been shown to be a primary driver for fission product release (Demkowicz et al., 2015; Harp et al., 2018a,b; Stempien and Demkowicz, 2020). The AGR program's recent PIE has provided insight on the release of select fission products

Table 3 Summary of compact average irradiation conditions for AGR-2 capsules.

Capsule ID	Kernel type	Burnup (%FIMA)	Fast neutron fluence (10^{25} n/m^2) ^a	TAVA ^b temperature
Capsule 6	UCO	7.26–10.81	1.94–2.73	987–1129 °C
Capsule 5	UCO	10.07–12.88	2.91–3.42	1040–1141 °C
Capsule 3	UO ₂	9.01–10.69	3.05–3.53	996–1062 °C
Capsule 2	UCO	10.80–13.15	2.88–3.47	1194–1296 °C

^aE > 0.18 MeV.^bTime-average volume-average.**Fig. 2** Capsule's average fission product release fraction of ⁹⁰Sr and ¹⁵⁴Eu for the AGR-2 experiments, open symbols for ¹⁵⁴Eu are values derived from minimum detectable activity. Image courtesy of John Stempien, INL.

by providing an effective mass balance of the fission products in the capsule, capsule components, and compacts to determine the extent of release over a range of irradiation conditions (Demkowicz et al., 2015; Stempien and Demkowicz, 2020). The AGR-2 irradiation experiment explored a range of Time-Average Volume-Average (TAVA) temperatures (i.e., the irradiation temperature of a fuel compact and constituent particles is characterized by the calculated temperature averaged over time and through the entire compact). The AGR-2 PIE focused on four capsules (Capsules 2, 3, 5 and 6) with Capsule 2 representing the highest temperature, with compact average TAVA temperatures of 1194–1296 °C compared to average TAVA temperatures of 987–1141 °C for all other capsules. The AGR-2 capsule-level release behavior of select fission products is described by Stempien and Demkowicz (2020). Outside of high-temperature Capsule 2, most radioisotopes remain well retained. Cesium is shown to be well retained, even in Capsule 2, with ¹³⁴Cs release fractions $\leq 8.74 \times 10^{-5}$ where a single particle's inventory is $\sim 2\text{--}3 \times 10^{-5}$. However, a temperature dependence is observed for capsule-level fractional release of ⁹⁰Sr, ¹⁵⁴Eu, and to a lesser extent, ^{110m}Ag. Fig. 2 shows the capsule average fission product release fraction of ⁹⁰Sr and ¹⁵⁴Eu for the AGR-2 experiments (Stempien and Demkowicz, 2020). There is a clear increase in release fractions for ⁹⁰Sr and ¹⁵⁴Eu at higher temperature (Capsule 2, capsule average TAVA temperature is 1252 °C), indicating a temperature-dependent release process through intact TRISO layers. Several models have been developed to predict fission product release through the TRISO layers. These models are dependent on both the diffusivity of the radioisotopes of interest, reflecting the temperature dependence, and the neutron fluence for the irradiation. The uptake of fission products into the SiC layer was shown to be proportional to the neutron fluence (IAEA, 1997). Because concentration gradients are drivers for diffusion, it is reasonable to hypothesize that the increased uptake with increased SiC layer radiation damage increases the effective diffusivity in the SiC layer. This would be expected to impact overall release, because diffusion in the SiC layer is rate limiting. For example, the diffusivity (diffusion coefficient) of silver, cesium, and strontium in PyC is 100–1000 × greater than in the SiC layer at 1100 °C (IAEA, 1997).

While ^{110m}Ag is not a high-yield fission product, the release of silver has been a point of much interest over the history of the TRISO fuel development due to its unique release: in some cases, a majority of the silver inventory is released (Harp et al., 2018a,b; Stempien and Demkowicz, 2020). Despite the extent of release, silver is considered an occupational hazard and not a hazard to the public (NRC, 2004). Silver does not form a stable oxide or carbide and is readily released from both UO₂ and UCO kernels. Therefore, silver is available to diffuse through the TRISO layers. The release of silver from intact particles during operation has been suggested to be impacted by the microstructure of the SiC layer, with more-equiaxed, fine-grained SiC layers retaining silver better than columnar-grained SiC layers with grains extending greater than half the thickness of the SiC layer (Petti et al., 2003). Observations of microstructure-related differences in silver release have been observed in safety-tested compacts from the AGR-1 PIE effort. However, a difference in grain size relationship is observed during safety-testing at 1800 °C relative to historic behavior during operation as TRISO particles with SiC layers of similar grain shape but a finer grain size showed greater additional release relative to

larger-grained SiC layer variants (Gerczak et al., 2016). Ultimately in pile silver release is tied to irradiation temperature. The irradiation experiments highlight an apparent critical temperature of $\sim 1100^\circ\text{C}$ above which silver retention decreases significantly (NRC, 2004) this is visualized in Fig. 3. Fig. 3 shows the compact-average retention for $^{110\text{m}}\text{Ag}$ from AGR-2, highlighting the perceived irradiation temperature dependence on silver release taken from compact gamma analysis (Harp et al., 2018a). The complete temperature dependence is yet to be resolved.

Particle failures

The typical behavior of TRISO fuel during irradiation is formation of fission gas bubbles in the kernel and radiation-induced kernel swelling as well as radiation-induced shrinkage of the buffer and associated internal tearing of the buffer away from the IPyC layer. The ideal TRISO particle response is shown in Fig. 4 with the IPyC, SiC, and OPyC layer remaining intact (Hunn et al., 2015a). This response leads to successful retention of most radionuclides during operation and during safety testing (Demkowicz et al., 2015). However, this behavior is not always realized and, in some situations, particle failure is observed.

The nature of a TRISO particle failure dictates the release of specific radionuclides. Typical particle failures can be described by two general classes: failed-TRISO particles and failed-SiC particles. Failed-TRISO particles are defined by the failure of the normal retention properties of the IPyC, SiC, and OPyC layers, providing a direct pathway for radionuclide release; this can happen either prior to or during irradiation. A major manufacturing defect or a particle whose TRISO layers are cracked during post-fabrication handling is known as an exposed kernel defect and is an example of TRISO particle failure. Overpressurizing a particle during irradiation or excessive radiation-induced layer shrinkage can also lead to this type of failure. This failure type is generally indicated by concurrent release of fission gases, volatile fission products, metallic fission products, and other radionuclide species from the kernel. Failed-SiC particles are generally described as particles with a compromised SiC layer and at least one intact pyrocarbon (PyC) layer to remain gas tight. Failed-SiC particles release volatile and metallic fission product species that diffuse through PyC; they generally have good retention of the noble fission gases Kr and Xe. Release of fission products from failed particles is notably higher than release from intact particles. However, the release can be variable and gradual, particularly as the kernel stabilizes a measurable fraction of many fission product species (depending on the local oxygen potential), thus inhibiting their release.

Holistic measurement of fuel performance and quality is represented by R/B on larger length scales such as the capsule or fuel element level (i.e., from a pebble or from a compact) and is a measurement used to assess the performance of the fuel during irradiation. The R/B from a fuel element is similarly defined as the released fraction of a specific isotope vs. the amount produced during irradiation. In-pile R/B measurements are frequently made of noble fission gases such as ^{85}Kr , which are not condensable in sweep gas or coolant. The R/B signal can indicate any of a number of phenomena during irradiation. In particular, elevated baseline R/B signals can imply a high level of dispersed uranium contamination outside the SiC layer in the matrix and OPyC. Fission of dispersed uranium outside the SiC layer contributes to release of the fission products and fission gas into the primary circuit of the reactor, as they only have to diffuse through the OPyC and/or matrix and are not held up by the rate-limiting SiC layer. The online monitoring of fission gas R/B can also indicate complete TRISO layer failure due to fabrication, failure during irradiation, or the presence of other exposed kernel defects after manufacturing. During online fission gas monitoring, acute increases in R/B of fission gases can indicate the presence of complete TRISO failures where no gas-tight layers remain intact.

The R/B analysis provides confidence in confirming complete TRISO failure and estimating the number of exposed kernels during service. So, it is significant that modern TRISO fuel irradiations have had very low in-pile R/B measurements, indicating

Fig. 3 Decay-corrected, measured-to-predicted $^{110\text{m}}\text{Ag}$ activity ratios of compacts from each AGR-2 capsule as a function of the TAVA irradiation temperatures. Lower values indicated less $^{110\text{m}}\text{Ag}$ retention and greater release from the compacts. Image courtesy of J. Harp.

Fig. 4 Typical response of UCO TRISO fuel particle architecture to irradiation in the AGR-1 irradiation experiment. An as-fabricated particle cross section is shown on the left and an as-irradiated particle cross section is shown on the right.

exceptional performance. For example, the Chinese fuel HTR-PM irradiation had a $^{85\text{m}}\text{Kr}$ R/B of $2.4\text{--}3.3 \times 10^{-9}$ (single particle equivalent 1.1×10^{-7}) with an in-pile failure fraction of $\leq 5.0 \times 10^{-5}$ at 95% confidence. The US AGR-1 irradiation showed $^{85\text{m}}\text{Kr}$ R/B = $0.2\text{--}2 \times 10^{-7}$, demonstrating an in-pile failure fraction of $\leq 1.1 \times 10^{-5}$ at 95% confidence, and the German HFR-5/6 irradiations showed $^{85\text{m}}\text{Kr}$ R/B = $1.7\text{--}9.0 \times 10^{-7}$, demonstrating an in-pile failure fraction of $\leq 5.1 \times 10^{-5}$ at 95% confidence. For all these irradiations, the R/B analysis indicates that no complete TRISO layer failures occurred during irradiation (Demkowicz et al., 2019; Kania et al., 2013).

Particle failures have the potential to significantly contribute to the accident source term. High-quality fuel is defined as having “very low particle failure rates during irradiation with failure fractions $\sim 10^{-5}$ (upper bound at 95% confidence)” (Demkowicz et al., 2019). As-fabricated defects can contribute directly to the in-pile failure fraction. Acceptable as-fabricated defect fractions (which are low, but are not zero) vary based on reactor design and regulatory expectations. Of particular issue are exposed kernel defects, which provide an immediate pathway for release of fission products not retained in the Kernel. Defective particles can be present due to numerous factors. Observed as-fabricated defects include soot inclusions, metallic inclusions, missing coating layers, cracked coating layers, and other anomalies. With the exception of cracked coating layers, most defects are attributed to the particle coating process, although cracked particles can be generated also during the compacting stage or during particle handling. Cracked particles are considered exposed kernel defects and can release fission products readily. Historically, the compacting process has been observed to fracture particles (Minato et al., 1998). This is not unexpected since the particles are subjected to elevated pressures—up to ~ 9000 lb./in² in AGR-2 (Pappano and Hunn, 2008)—during compacting, and the particle bed has limited opportunities to reconfigure itself for stress relief during the compacting process. However, particle fracture can be avoided or limited, as was shown in AGR-2, in which the as-fabricated defect fraction for particles before and after compacting were roughly equivalent (Hunn et al., 2010).

Processing defects such as soot and metallic inclusions may not fail immediately or at all during service. However, these defects have been shown to lead to particle failure, with the resultant release of fission products and actinides (Hunn et al., 2018b). Fig. 5 shows an example of an unusually exaggerated as-fabricated soot inclusion in a TRISO particle which resulted in a porous SiC layer. While this compromised SiC layer survived throughout irradiation, a small crack developed during safety testing at 1600 °C. The kernel was removed during the post examination task of deconsolidation-leach-burn-leach (Hunn et al., 2016). Fig. 6 shows an example of a molybdenum inclusion in the SiC layer of a TRISO particle (from fabrication) (Hunn, 2009), along with a suspected particle failure due to molybdenum attack of the SiC layer from the AGR-2 irradiation experiment after safety testing at 1800 °C (Hunn et al., 2018b). Both inclusion defect particles shown here maintained gas tightness during irradiation and did not fail until being subjected to the severe conditions of a high-temperature safety test.

In-pile particle failure

Although modern TRISO fuel has shown that the observed failure rates in pile are within acceptable limits, understanding the failure mechanism associated with the few observed failures contributes to optimization of fuel fabrication and quality control methodology which help to ensure safe, efficient operation, as well as prediction of safe operating conditions. Over the decades of coated particle fuel development, multiple failure mechanisms have been identified, and designs and operating conditions have evolved to

mitigate certain failure mechanisms. This highlights the continued need to understand particle failure mechanisms, both in-pile and under abnormal accident conditions, so that failure rates can be limited and appropriate operation can be ensured. Irradiation testing and safety testing (in core or post-irradiation) are important for determining the conditions and likelihood for failure. The particle failure mechanisms responsible for appreciable fission product and radionuclide release are understood by (1) determining the nature of the fission product release (e.g., fission gases only vs. fission gases and metallic fission products) and (2) through destructive PIE to observe the specific failure mechanisms.

Pressure vessel failure

Noble fission gases (Kr, Xe) and carbon monoxide (CO_(g)) are the primary contributors to internal gas pressure in the standard TRISO-coated oxide kernel particle. Fracture of the PyC and SiC layers can occur if the internal pressure exceeds the yield strength of the coating layers. This fracture can severely degrade particle integrity, leading to abrupt failure of the TRISO layers and exposure

of the kernel, providing a direct path for fission product and radionuclide release. This failure mechanism is known as *pressure vessel failure*. Fig. 7 shows an example of this failure mode in a UO_2 kernel TRISO fuel particle (Homan and Long, 1976).

The fission gas pressure is dependent on kernel chemistry (e.g., oxide vs. carbide), and irradiation conditions (primarily burnup and temperature). Release of Kr and Xe fission gases from the kernel is described above and in Eq. (1). For UO_2 kernel fuel, the $\text{CO} + \text{CO}_2$ gas pressure dominates at burnups below $\sim 9\%$ fission per initial metal atom (FIMA) (Barrachin et al., 2009). The equilibrium $\text{CO} + \text{CO}_2$ gas pressure is tied to the initial oxygen-to-metal ratio (O/M) (e.g., uranium, plutonium) (Besmann, 2010). In general, in the absence of a gettering phase, the total $\text{CO} + \text{CO}_2$ gas pressure increases with increasing O/M ratio as the fuel becomes hyperstoichiometric at higher burnups and fissile material is consumed liberating oxygen (Besmann, 2010). An empirical relationship for oxygen released from the kernel in UO_2 was developed by Proksch et al. (1982) and is given in Eq. (5), where O/F is the fraction of oxygen released in atoms per fission, t is irradiation time (s), and T is time-averaged particle surface temperature (K) (Proksch et al., 1982; Hales et al., 2013). In Eq. (5), the fraction of released oxygen is assumed to convert to $\text{CO}_{(g)}$ by reacting with the carbon buffer layers (Hales et al., 2013). When equilibrium conditions due to high temperatures and long irradiation times are met, the O/F reaches a thermodynamic limit of 0.4 (Proksch et al., 1982). Fission gas buildup is primarily accommodated through gas migration into the excess void space in the buffer. The buildup of $\text{CO}_{(g)}$ gas pressure limits or influences the design envelope (burnup, temperature, temperature gradient) for UO_2 kernel TRISO. Control of the $\text{CO}_{(g)}$ gas pressure is one of the primary drivers for the use of UCO kernel fuel, particularly when higher burnups are sought, as in prismatic fuel designs (Petti et al., 2003; Maki et al., 2007). The addition of the uranium carbide phase, or the use of oxygen getters such as SiC or ZrC, buffers the formation of $\text{CO}_{(g)}$ and reduces overall $\text{CO}_{(g)}$ pressure by effectively lowering the O/M ratio so that it is much less dependent on irradiation conditions. For context, in the PuO_2-x fuel system, the total gas pressure can be reduced by ~ 3 orders of magnitude through oxygen getters (Besmann, 2010). This approach mitigates the risk of failure by internal pressurization and allows for higher burnups to be achieved.

$$\frac{O}{F} = \frac{t^2}{(1.211 \times 10^{10}) 10^{\frac{8500}{T}}} \quad (5)$$

Pressure vessel failure is an example of mechanical failure. The TRISO particle architecture is also intended to provide some resiliency to SiC fracture. Radiation-induced shrinkage of the OPyC layer has been modelled to put the SiC layer under compression when under irradiation. This compressive stress state is expected to decrease the probability of SiC mechanical failure (Miller et al., 2006; Powers and Wirth, 2010). However, recent PIE efforts suggest that this effect may not be applicable in all conditions experienced by the fuel, as separation has been observed between the SiC and OPyC layers, suggesting the OPyC layer does not always keep the SiC under compression (Hunn et al., 2014, 2015b, 2019a).

Kernel migration

Kernel migration, or the *amoeba effect*, is the net movement of the fuel kernel along the temperature gradient within a particle. Excessive migration can lead to kernel interactions with the IPyC or SiC layers, compromising the integrity of the fuel particle. Fig. 8 shows an example of excessive kernel migration in a UO_2 TRISO fuel particle (Homan et al., 1977). Work by Wagner-Löffler (1977) provides an overview of the mechanisms driving the kernel migration phenomenon. Kernel migration occurs due to the transport of carbon from the hotter side of the kernel to the cooler side. In carbide kernel TRISO fuel, the transport is thought

Fig. 7 Example of a pressure vessel failure in UO_2 TRISO fuel.

Fig. 8 Examples of the amoeba effect on kernel migration.

to be due to solid-state diffusion of carbon across the kernel. For oxide fuel particles, the mechanism is thought to be dependent on a higher concentration of $\text{CO}_{(g)}$ forming on the hotter side of the particle and diffusing in a gaseous state around the kernel to the cooler side. A complimentary mechanism supporting net transport of oxygen to the hot side must occur. Possible pathways are (1) solid-state diffusion of oxygen back through the kernel (oxygen liberated from $\text{CO}_{(g)}$ decomposition) or (2) gas phase $\text{CO}_{2(g)}$ transport back to the cool side. The transport of oxygen back to the hot side is expected to be the rate-limiting step. This mechanism depends on the oxygen potential in the systems, the control of which can mitigate the potential for kernel migration (Besmann, 2010; Bullock and Kaae, 1983). This has been confirmed in UCO kernel TRISO fuel, in which the oxygen potential is low enough that kernel migration is not observed (Homan et al., 1977), consistent with oxygen transport being the rate-limiting mechanism for this phenomenon. The minimum amount of carbide phase (UC_x) in UCO TRISO fuel needed to limit kernel migration by suppressing $\text{CO}_{(g)}$ production has been calculated at 5.1–5.5 mol% for 15.5% enriched fuel taken to 16.1% FIMA (McMurray et al., 2017).

An empirical relationship for kernel migration in UO_2 TRISO is shown in Eq. (6) (Maki et al., 2007), where δ_{MIG} is the migration distance (m), KMC is the kernel migration coefficient ($\text{m}^2\text{-K/s}$), T is the temperature, and ∇T is the associated temperature gradient. Comprehensive models to predict the amoeba effect have been developed by Özdere Güllol et al. (2008) and Choi and Lee (2006). The KMC follows an Arrhenius relationship, and the term KMC/T^2 varies from 1.00–1.70 over the range 1100–1300 °C (Maki et al., 2007). The higher power densities and related thermal gradients in prismatic fuel elements relative to pebble fuel designs can lead to a greater propensity for kernel migration. This is one motivation for using the UCO kernel (with its lower oxygen potential and reduced kernel migration tendency) for prismatic fuel designs, in which thermal gradients tend to be higher than in pebble-bed designs.

$$\frac{\delta_{\text{MIG}}}{T^2} = \int \frac{\text{KMC} \cdot \nabla T}{T^2} d\tau \quad (6)$$

SiC corrosion by fission products and $\text{CO}_{(g)}$

The SiC layer is a structural component in the TRISO particle design and the primary barrier to the release of metallic fission products not retained in the fuel kernel. The SiC layer has been observed to be susceptible to corrosion by rare earth fission products, palladium, and $\text{CO}_{(g)}$, and this can result in particle failure (IAEA, 1997; NRC, 2004; Grübmeier et al., 1977). The nature of the interaction of fission products and gases with the SiC layer can depend on the internal structure of the TRISO particle, specifically, whether or not the SiC layer is exposed due to IPyC cracking (Minato et al., 1991; Hunn et al., 2016).

Palladium is a high-yield fission product that does not readily form a stable oxide or carbide, as such it is released from both UCO and UO_2 TRISO fuel particles. Though in low-enriched UO_2 TRISO fuel, the formation of noble metal inclusions was observed

to stabilize a small fraction of the palladium inventory in the kernel (Tiegs, 1982). The palladium released from the kernel has been observed to interact with the SiC layer in different ways depending on the internal structure of the TRISO particle.

The depth of palladium penetration into the SiC for general SiC interactions has been observed to be temperature dependent, following an Arrhenius relationship (Tiegs, 1982; Stansfield et al., 1983), and related to the amount of palladium released from the kernel (Minato et al., 1990). The Pd/SiC interaction can occur grossly over the circumference of the IPyC/SiC interface, or it can be isolated to specific regions of the SiC layer (which is most damaging). Gross palladium interaction effectively thins the SiC. Temperature gradients across the TRISO particles can also influence general palladium interactions with a preference of palladium pile up and penetration on the “cold” side of the particle subjected to a temperature gradient (Minato et al., 1990).

Through-layer SiC failures are frequently associated with localized palladium corrosion (Minato et al., 1990; Hunn et al., 2016). A holistic understanding of the relationship between IPyC cracking and localized corrosion was developed from the multiscale PIE approach adapted by the U.S. AGR program to confirm the nature of particle failures. The multiscale approach leverages capsule-level analysis, compact-level analysis, and individual-particle gamma analysis in conjunction with micro-X-ray computed tomography (μ XCT) and informed destructive materialography techniques (Hunn et al., 2016). This approach has been effective in isolating failed particles, finding localized failure(s) in the particles, and explicitly determining the responsible failure mechanisms (Hunn et al., 2016; Demkowicz et al., 2015). In the AGR-1 irradiation experiment, this PIE approach confirmed that local through-layer SiC attack by palladium was associated with particle failure and served as a fission product release pathway. The multiscale PIE approach linked incomplete buffer separation from the IPyC to the formation of IPyC cracks that exposed a small region of the SiC layer to higher palladium concentrations and promoted accelerated and localized palladium attack (Hunn et al., 2016). After this sequence occurs and a through-layer SiC failure appears, and the release of fission products typically limited by the SiC layer is possible. Fig. 9 visualizes this failure sequence (Hunn et al., 2016).

Corrosion of the SiC layer by high-yield rare earth elements is observed in TRISO particles with low oxygen content (O/U ratios ≤ 1.1). This O/U ratio is found in TRISO fuel with carbide kernels (e.g., UC_2). However, rare-earth SiC layer corrosion is not readily observed in UO_2 or UCO TRISO fuel compositions of current interest for HTGRs. In high carbide kernels there is insufficient oxygen to stabilize the rare-earth fission products (neodymium, cerium, praseodymium, and lanthanum) as oxides. These rare-earth elements are often co-located with palladium at the SiC layer in carbide kernel TRISO, suggesting similar transport behaviors within the TRISO particle (Homan et al., 1977; Tiegs, 1982).

Corrosion of the SiC layer by $CO_{(g)}$ is a potential failure mechanism in UO_2 TRISO and is not expected in UCO TRISO fuel due to $CO_{(g)}$ gettering. The SiC layer is generally protected by the IPyC layer that prevents excessive $CO_{(g)}$ exposure and corrosion under certain operating conditions. However, the SiC becomes susceptible to global $CO_{(g)}$ corrosion at higher temperatures associated with loss-of-cooling accidents or when the IPyC layer is compromised. Compromise of the IPyC layer protective properties can happen when it debonds or detaches from the SiC layer, possibly generating microcracks, or when macro IPyC cracks are present. The $CO_{(g)}$ corrosion mechanisms preferentially occur at SiC grain boundaries (Gerczak et al., 2020b; Minato et al., 1991), and the $CO_{(g)}$ /SiC reaction results in the production of volatile $SiO_{(g)}$, which transports to the cool side of the particle (Minato et al., 1991).

Fig. 9 X-ray tomography of AGR-1 particle with failed SiC from Compact 3-3-1 Particle 1 after 1700 °C safety testing following completion of AGR-1 irradiation test. The image reveals the failure sequence leading to a through-layer SiC failure. Image courtesy of John Hunn, Oak Ridge National Laboratory.

Localized CO_(g) corrosion often precedes mechanical failure of the SiC layer due to weakening and thinning of the SiC (Minato et al., 1991; Morris et al., 2018). The corrosion of SiC by CO_(g) is dependent on temperature, as evidenced by the increase in CO_(g) corrosion driven particle failures observed at increasing safety testing temperatures (Hunn et al., 2018b; Morris et al., 2018).

Thinning of SiC by palladium or CO_(g) corrosion increases the risk of particle failure via stress from internal pressurization (Miller et al., 2006). This has been observed empirically (Minato et al., 1991). The mechanistic fuel performance model, PARFUME, has been used to predict SiC layer fracture probability in response to different thinning scenarios which may occur by palladium and CO_(g) corrosion (Miller et al., 2006).

Summary

The identified particle failure mechanisms described in this article highlight the integrated nature of the TRISO fuel design. The many potential particle failure mechanisms described herein are well-understood. The efficacy of incremental design improvements made during the evolution of TRISO fuel have been verified in worldwide test irradiations and post-irradiation examinations. The irradiation testing highlights the importance of (1) controlling kernel chemistry to limit gas pressure and fission product transport, (2) ensuring the debonding of the buffer layer from the IPyC during irradiation, and (3) providing strong and crack free bonding of the IPyC to the SiC layer. In addition, as-fabricated particle defect fractions and particle damage during the fuel forming process must be held to an absolute minimum, and the irradiation stability of the matrix material must be high with minimum potential for cracking that may lead to externally-induced particle failure.

The understanding of the interconnected response and role of each TRISO particle component during irradiation has led to particle designs and fabrication approaches that have allowed modern TRISO fuel for HTGR applications to exceed performance targets for prescribed operational ranges. Failure rates better than of $\leq 5.1 \times 10^{-5}$ at 95% confidence have been obtained, thus proving the attainability of a goal of high-quality fuel performance under irradiation (Demkowicz et al., 2019). The achieved reduction of the fraction of particle failures in-pile elevates the importance of manufacturing high-quality TRISO fuel with low-defect fractions to ensure appropriate performance metrics are met (i.e., limit fission product release). The decades of TRISO fuel development and demonstration have shown the possibility for acceptable performance of TRISO fuel in HTGR reactors designed to realize the benefits of passive safety, industrial process heat applications and high thermal efficiencies for power production.

Introduction

This article serves as a companion to the article on research reactor fuel design and fabrication (Cole et al., 2021). That companion chapter defines and describes terms and fuel design features referred to in this article, such as plate-type fuel, monolithic fuel, dispersion fuel, fuel matrix, and fuel forms used in research reactor fuel (U_3O_8 , U_3Si_2 , U-Mo). The purpose of this article is to inform the reader of the unique set of requirements that research reactor fuels must meet and the synergistic relationship between fuel system irradiation performance, reactor performance, and operational safety. These requirements and their criteria constrain the fuel system choice to a handful of design options having specific characteristics and properties that enable research reactor designers and operators to successfully execute their unique missions. In particular, this article will focus on the performance attributes of plate-type fuel systems in high-power research reactors where the fuel margin to failure is reduced and understanding irradiation performance and failure behavior is most critical. Many lower power research reactors utilize the same fuel systems but operate significantly below the fuel safety limits. Reviewing fuel performance considerations for the high-power applications will best illustrate the phenomena of interest and challenges for research reactor fuel designs in general.

To this end, rather than organizing this discussion around specific fuel materials and cataloguing the irradiation behavior of each specific fuel type, which has been done in several excellent and comprehensive published reviews (Hofman and Snelgrove, 1994; Meyer et al., 2020; Kim, 2012), generic performance requirements will be emphasized, and the fuel system attributes needed to meet these requirements will be described. These descriptions are provided in the context of fuel system development and qualification to obtain regulatory approval for subsequent deployment to new or existing research reactors in the United States. Throughout the discussion, the impact of fuel degradation under irradiation on fuel integrity will be emphasized. Because the recent emphasis in the United States has been to qualify a new low-enriched uranium (LEU) U-10Mo (all alloy compositions are in weight percent) monolithic plate-type fuel, many of the examples provided will address that fuel design; but the principles illustrated will apply generally to the issues to be addressed in qualifying any fuel design (demonstrating acceptable fuel performance under design-basis operation and demonstrating sufficient knowledge of phenomena to adequately predict lifetime irradiation behavior). Finally, a general overview of the methodology used to test and qualify new fuel systems for use in research reactors will be described.

Research reactor fuel performance requirements

A fuel system must meet a set of performance requirements to ensure that a given reactor can effectively and safely meet its mission envelope. In the development and regulatory qualification of fuels for research reactors, data is collected to demonstrate that the fuel system meets these established performance requirements (Anon., 1988, 2009, 1996). Specific requirements are established to

*Retired.

ensure that the fuel maintains the following overall irradiation performance attributes throughout its service life. The requirements identified for research reactor fuel, in broad terms, are the following:

- Mechanical integrity—no cladding breach occurs under normal operating conditions or anticipated transients such that the cladding retains fission products.
- Geometric Stability—ability to maintain adequate system cooling under normal reactor operating conditions and expected transients, mainly by maintaining the coolant-flow channel gap (spacing between fuel plates).
- Stable and predictable behavior—the fuel exhibits consistent, predictable fundamental irradiation behavior over the anticipated range of operating conditions.

The fabrication processes utilized must produce a fuel system that encapsulates the fuel material and prevents the release of fission products to the environment (Cole et al., 2021). The cladding itself must resist corrosion and an excessive buildup of oxide on the surface under operational conditions (oxide will impede heat transfer from the fuel plate and could lead to exceeding fuel design temperatures). Additionally, the stress state of the fuel system and its implication on overall fuel system performance must be understood. Compressive and tensile residual stresses can build up in the fuel plate due to the heating and cooling of materials with different thermal expansion behavior, resulting in the fuel plate being nearer to the failure limits than anticipated. The following sections consider each of the major irradiation performance requirements in more detail and provide examples of testing, examinations, and modeling that are utilized to demonstrate that the fuel system meets those requirements.

Mechanical integrity

The robust structural integrity of the cladding ensures that the fuel does not breach under normal operating conditions and design basis transients, ensuring the fuel plate retains hazardous radionuclides. Mechanical integrity under normal operating conditions is demonstrated primarily through the successful testing of fuel plates up to the limiting conditions established by the specific reactor's fuel performance and safety analyses. This includes an adequate margin to cladding failure (or breach) supported by analysis using data from comprehensive microstructural characterization and post-irradiation examination (PIE). Maintaining mechanical integrity under anticipated transients is primarily demonstrated through blister threshold testing (details will be described later), which demonstrates the limiting fuel temperature to be used in safety analyses of reactors. The mechanical integrity of the fuel-plate system is evaluated both experimentally and with simulations using finite element analysis (FEA). Five criteria are used to demonstrate that the fuel system maintains adequate mechanical integrity under irradiation:

- Physical and mechanical properties related to fuel integrity for all constituents are known (melting point, modulus, strength, etc.).
- The fuel plate will not delaminate during normal operating conditions and anticipated transients.
- Mechanical responses of fuel core (uranium-bearing regions of fuel system), cladding, and any interlayers during normal operations and anticipated transients is established.
- Limits for fabrication defects are established.
- Water corrosion limits for the cladding are established.

Fuel performance modeling of thermo-mechanical behavior

It is widely recognized that fuel performance modeling can provide valuable information that would be infeasible, difficult, or cost prohibitive to obtain experimentally (Rest, 2012; Rabin et al., 2017). For instance, fuel performance modeling allows investigation of the fuel's sensitivity to variations in key geometric, operational, and materials property variables to improve the overall understanding of fuel behavior. Fuel performance modeling also provides valuable input for establishing manufacturing defect limitations, produces information useful for interpreting characterization and PIE results, and allows an assessment of important fuel phenomena, such as geometric changes, operational limits, and fuel failure mechanisms.

This understanding of the fuel mechanical response is established through thermomechanical modeling, incorporating the best available materials properties measurements and behavioral models. Behavioral modeling of fuel plates is a multi-physics problem, involving the integration of several tightly coupled phenomena. This multi-physics coupling inherently necessitates a consideration of many parameters to assess the overall fuel performance. Stresses, strains, deformations, and temperatures are evaluated together to provide an accurate performance assessment of the fuel plate throughout its service life.

Sensitivity studies are conducted to isolate the effect of individual variables on overall irradiation performance. Parameters representing various geometric, operational, and property-related variables consider a wide range of design and operational constraints required by the specific reactor. Geometric parameters include fuel thickness, shape of fuel corners, fuel offset, fuel curvature, etc. Operational parameters include cooling rate, fission profile, mechanical constraints, etc. And finally, property related parameters include thermal properties degradation, swelling, creep, etc. These parameters are comparatively evaluated to determine the most influential parameters, while studying the performance of plates for what-if scenarios.

To accurately assess the integrity of the fuel, the thermal and mechanical responses of the monolithic U-10Mo fuel have been modeled over the entire lifecycle of the fuel plates to account for cumulative effects. Lifecycle stages include foil fabrication, plate

bonding, irradiation, and post irradiation testing. The fidelity of model output can be further refined through continual validation using experimental fuel performance data derived during testing and PIE (e.g., fission gas bubble distributions and dimensional changes as a function of burnup). The reduction of uncertainties with a growing body of critical parameter measurements increases the ability of the models to evaluate conditions under which fuel plate failure is likely to occur. Focused evaluation of critical properties identified by the modeling provides an efficient method of streamlining irradiation performance assessments.

As an example of the utility of fuel performance modeling, Fig. 1 illustrates the formation of a pillow in an irradiation-tested U-10Mo fuel miniplate (i.e., a small but prototypic fuel-plate design used for irradiation testing). Along with the image of the fuel plate are images that were produced using the FEA simulation at end of life (EOL), following reactor shutdown, demonstrating that temperatures stresses and fission-gas-induced porosity are greatest adjacent to the region exhibiting the pillowing behavior, which suggests that the genesis of the behavior is a combination of factors including stress state, and porosity distribution (Medvedev et al., 2018). Comparative assessment of modeling results with experimental observations can provide a more comprehensive and mechanistic understanding of irradiation performance that experiments alone may fail to reveal.

Cladding corrosion

Limits on fuel fabrication defects are based on experimental irradiation performance data and theoretical calculations of oxide growth and cladding corrosion resulting from an assumed single-sided debond condition (i.e., separation of the cladding plate from the fuel core) that greatly reduces heat transfer from the debonded face of the plate. The use of aluminum-clad research reactor fuel in water leads to the formation of a corrosion product layer with low thermal conductivity. The growth rate of the layer varies with reactor operational parameters (plate power and coolant flow) and reactor-specific water chemistry. If the fuel plate power and coolant channel flow are not properly matched in high-performance reactors, the corrosion layer thickness can increase rapidly. If the corrosion layer thickness is allowed to exceed a point where the temperature gradient across the layer is greater than approximately 119 °C, oxide spallation is likely to occur, exposing fresh aluminum to further rapid oxidation (Pawel et al., 1990; Rabin et al., 2017). Extended exposure to conditions where spallation occurs may result in the complete oxidation of the aluminum cladding. If an oxide surface layer does not spall and grows locally to a sufficient thickness to increase the fuel temperature beyond the blister threshold temperature, blistering may occur.

Geometric stability

The geometric stability of the fuel is essential to preventing coolant channel blockages through an increase in fuel plate thickness or through the mechanical collapse of a coolant channel. Five criteria must be met to demonstrate geometric stability.

- Geometry of the fuel must be maintained during normal operating conditions and anticipated transients.

Fig. 1 Irradiated LEU U-10Mo monolithic miniplate images showing: (a) a pillow-type failure (b) a neutron radiograph of the failed plate along with the FEA model output of (c) the fuel centerline temperature at end of life (d) the maximum principal stresses at shutdown (e) the end-of-life fuel porosity, and (f) regions with porosity interconnection. Adapted from Medvedev PG, Ozaltun H, Robinson AB and Rabin BH (2018) Shutdown-induced tensile stress in monolithic miniplates as a possible cause of plate pillowing at very high burnup. *Nuclear Engineering and Design* 328: 161–165.

- Data must be documented for material properties that affect geometric stability and thermal-hydraulic performance as a function of increasing fuel burnup.
- Fuel performance and structural stability must be maintained so that reactor-coolant flow maintains fuel plate heat transfer and/or temperatures within the reactor safety envelope.
- Plate movement caused by the hydraulic pressure differential must not compromise ability to cool the fuel.
- Changes in channel gap dimensions must not compromise the ability to cool the fuel plate.

The fuel plates are typically assembled in highly compact fuel assemblies with narrow coolant channels and high flow rates. For this reason, any features that develop in the fuel plate that restrict this flow can lead to plates overheating (resulting in excessive oxide buildup) and breaching. Thus, it becomes critical that the fuel maintains geometric stability under these design conditions and resists any tendency to undergo unanticipated dimensional changes due to imposed thermo-mechanical forces.

During irradiation, coolant channel gaps must be maintained within as-designed tolerances to ensure that fuel plates are adequately cooled. Changes in coolant channel gap width may be caused by flow-induced stress, relaxation of stress introduced into fuel plates during fabrication, blistering, pillowing/delamination, or breakaway fuel swelling. These behaviors are to be avoided because they can compromise the ability to cool the fuel (in addition to leading to cladding beach).

Aluminum-clad, plate-type research reactor fuel fails at elevated temperatures through the formation of small, raised pockets of fission gas termed as “blisters,” which result in a geometry change that can impede coolant flow. Therefore, blister threshold data can be used to establish safe operating temperature limits during both normal and off-normal operating conditions. Blister threshold testing is a destructive process, usually performed in conjunction with PIE of tested fuel plates. The test is typically performed on full, intact plates and can indicate the presence of defects, high levels of porosity in the fuel, or an agglomeration of fission gas bubbles. During the testing, the fuel plate is heated to an elevated temperature (typically between 300 and 550 °C) in specific increments, holding at each temperature for a fixed period of time (~20 min) and then visually examined to detect the formation of blisters on the fuel plate surface. Results of this test are used to assess margins to failure for various accident scenarios analyzed in reactor-specific safety bases and to ensure that the geometry is maintained under anticipated transient conditions.

A more detailed, quantitative examination of out-of-pile fuel plate stability can be accomplished utilizing a testing apparatus such as a generic test-plate Assembly (GTPA) (Rabin et al., 2017). The GTPA is a modular mechanical assembly that can be used to house different types of instrumented test plates, in a thermal-hydraulic test apparatus, such as the Hydro-Mechanical Fuel Test Facility (HMFTF) located at Oregon State University in the United States (see Fig. 2). Test results can be used to compare the structural characteristics and dynamic response of plates produced through different fabrication methods (e.g., roll bonding and hot isostatic press (HIP) bonding), different cladding materials or alloy heat treatments, and different fuel types (e.g.,

Fig. 2 Oregon State University's Hydro-Mechanical Fuel Test Facility (HMFTF) and test section with the GTPA location indicated. Courtesy Professor Wade Marcum, Oregon State University.

monolithic or dispersion). The plates are tested at selected flow rates under sub-cooled fluid-state conditions that represent reactor-coolant temperatures and pressures.

The objectives of the tests are to:

- Identify the flow conditions that induce the onset of elastic plate deformation for each fuel plate material.
- Identify the approximate flow conditions necessary to produce an ultimate plate failure in either a static (large plastic deformation) or dynamic (plate vibration) state.
- Provide test data for validation of computational models of the static and dynamic response of plates and plate assemblies to flow, enabling the modeling of more complex systems.

Understanding the hydraulic flow behavior of research reactor fuel in prototypic elements is also critical to ensure that the fuel system behaves in a predictable manner and is not susceptible to vibration-induced resonance and gross thermo-mechanical deformations when placed in service. The models established to predict this behavior can also be used to aid in the design of prototypic experiments for the regulatory qualification of new fuel systems as they are developed and tested.

Stable and predictable behavior

Research reactor fuel plates must operate in a stable and predictable manner, despite perturbations in operating conditions. The key phenomena that can impact the dimensional stability and robustness of a fuel plate during irradiation are fuel swelling (due to fission product accumulation, phase transformation to less-dense phases, or radiation-enhanced diffusion) and fuel relocation resulting from irradiation-induced creep. Breakaway swelling occurs in some fuels when fission gas bubbles coalesce to form large gas pockets, which under decreased surface tension easily expand and cause a rapid increase in fuel-plate thickness upon further use. Large areas on the fuel plate with increased thickness due to “blistering” or “pillowing” are unacceptable due to the potential to impact mechanical integrity or coolability. Pre- and post-irradiation dimensional measurements and detailed microstructural characterization are the primary tools used to document the evolution of fuel condition during irradiation and the formation of microstructural features that indicate the onset of unstable behavior.

Because the fuel core is physically bonded to the cladding (or to fuel-cladding interlayers, for some designs) to improve heat conduction, it is critical for the fuel to behave in a predictable manner. Pure uranium has highly anisotropic properties at room temperature due to its orthorhombic crystal structure. The impact of this anisotropic structure can manifest with increasing fuel burnup as non-uniform dimensional changes. The addition of alloying elements to the uranium can stabilize a body-centered cubic (bcc) fuel phase (e.g., Mo) that has isotropic behavior; such stabilization is preferred in monolithic fuel designs, which do not have the surrounding Al matrix of a dispersion fuel to reduce the impact of individual fuel particle swelling on the behavior of the bulk fuel core.

Five requirements have been established to demonstrate stable and predictable behavior:

- Fuel performance is known and predictable for the expected range of fuel composition and impurities, processing parameters, and microstructure for all credible environmental and irradiation conditions.
- Physical properties and fuel attributes that are important for the analysis of fuel stability under irradiation are documented.
- Fuel swelling behavior is within the stable swelling regime (linear and predictable).
- Compatibility of fuel with reactor coolant is established to cover the case where a small cladding breach may occur under normal operation conditions.
- Irradiation behavior on scale-up (geometric and fabrication) is predictable.

In terms of quantifying the accumulated irradiation damage within fuel specimens, the primary parameter of interest is the percent burnup (i.e., the relative number of initial fissile atoms consumed), which is frequently and more conveniently expressed in terms of fission density (fissions cm^{-3}). Fission density removes the bias inherent in ^{235}U burnup values due to uranium enrichment or heavy metal atom fissions. For that reason, fission density allows a more direct comparison of burnup levels between highly enriched uranium (HEU) and LEU fuels. Therefore, fission density is often considered a more relevant fuel irradiation performance measure than burnup and is a critical operating parameter that defines the lifetime of the fuel as well as an important consideration for reactor fuel management.

Irradiation-induced dimensional changes

During irradiation, the swelling of the fuel core occurs due to an accumulation of fission products and, to a much lesser extent, irradiation damage. The swelling behavior of the fuel material is a defining attribute of the fuel form that determines its suitability for use in a specific nuclear application. Moderate amounts of swelling can be accommodated in design, provided the swelling behavior is stable and predictable for the range of fuel operating conditions and provide sufficient operating margin.

The fission products responsible for fuel swelling can be broken into two general categories: solid and gaseous. While swelling due to solid fission products is relatively easy to project and is relatively stable, swelling due to gaseous fission products can manifest in a variety of ways and is often the source of nonlinearity in the swelling behavior. For dispersion fuels, the swelling is largely accommodated by the presence of a ductile Al matrix. In the case of U-Mo alloy fuels (both monolithic and U-Mo dispersion in

an Al matrix), the incorporation of fission gases within U-Mo leads to a precipitation of discrete nano-scale fission gas bubbles dispersed throughout the fuel. Gamma-phase U-Mo exhibits unusual behavior wherein these nano-scale fission gas bubbles form a three-dimensional, highly ordered fission gas bubble superlattice that imparts this phase with excellent fission gas retention characteristics and stability against fission gas bubble coarsening. As burnup increases, microstructural changes due to polygonization/recrystallization, lead to the formation of discrete μm -scale gas bubbles, initially located along grain boundaries, and later dispersed through the fuel.

As fission gas production in the fuel increases with burnup, most fuel materials have a tendency towards an accumulation of the gas into the μm -scale bubbles that eventually interconnect and lead to swelling that increases more rapidly with further increases in fission density. Breakaway swelling is a term that has been used historically to define a rapid or unpredictable transition to high swelling behavior following an initial regime of stable fuel behavior. If the fuel system exhibits breakaway swelling, which has sometimes been seen in dispersion fuels, a fission density threshold that defines the onset of this breakaway swelling must be identified during the fuel development effort. Examples of fission gas bubble development in a U-10Mo and U_3Si_2 fuel respectively are illustrated in Fig. 3. The as-fabricated U_3Si_2 fuel particles shown in Fig. 3b have become amorphous during irradiation.

The readers should note that although frequently used interchangeably, “fuel swelling” and fuel plate “thickness change” are not the same and involve different phenomena. Swelling is an increase in volume that occurs isotropically (in its thickness, length and width) due to the formation of gaseous and solid fission products. However, in plate-type fuel, fuel deformation occurs primarily in its thickness due to the mechanism of irradiation-induced creep, which results in strains due to mass relocation away from the constrained edges as the fuel swells. The observed plate thickness changes are a superposition of both volumetric fuel swelling and irradiation-induced creep strains. Measured local thickness changes historically used to calculate strains are often referred to as fuel swelling; however, the measured thickness change always contains contributions from both irradiation-induced creep and volumetric swelling.

The stresses that develop due to constraints imposed by the cladding produces fuel creep. The resultant material relocation and stress relaxation can influence the microstructural evolution including recrystallization, grain subdivision, and gas bubble growth, as the internal stress state is altered. This synergistic interaction between the evolving microstructure and the creep deformation behavior has an impact on all fuel performance parameters, including mechanical integrity, geometric stability, and stable and predictable behavior.

Microstructural changes

A large part of functional fuel design is to allow heat removal as efficiently as physically possible. Changes in the fuel microstructure can reduce the effectiveness of heat transfer (by reducing thermal conductivity through the fuel), contribute to an embrittlement of the fuel, consequently affecting its mechanical integrity, and introduce phases that have unstable and unpredictable behavior (e.g., break-away swelling). The fuel temperatures in research reactor fuels is low enough that many of the microstructural processes occurring in the fuel are being driven by the creation and evolution of the radiation-induced defect structures in the absence of a significant thermal component. The fuel microstructure evolves with the creation of a high density of fission gas filled gas bubbles, solid fission products and crystal defects such as radiation-produced dislocation structures. As more damage accumulates, fuel materials can lose long-range order and become amorphous, which is most typical for intermetallic compounds. Amorphous materials inherently have a greater free volume, and gas diffusion in this structure is accelerated. So, as a general rule, the resistance to bubble formation and unstable growth in an amorphous fuel is lower than in a fuel that remains crystalline. Amorphization occurs at lower fission density in oxide (U_3O_8) and intermetallic fuels (UAl_x , U_3Si and U_3Si_2) compared to an alloy fuel, such as U-Mo, and the loss of crystallinity can be more rapid with an increasing volumetric power density. This characteristic, along with a relatively high uranium density, has motivated the development of U-Mo fuel for research reactors.

Fig. 3 Scanning electron microscope images of fission gas bubble formation in (a) a monolithic U-10 Mo fuel and (b) a U_3Si_2 fuel at moderate burnup levels ($< 5 \times 10^{21}$ fissions cm^{-3}).

For U-Mo alloys, as the number of crystalline defects increase with fission density, the thermodynamic driving force is for the microstructure to reconfigure into a lower energy state. This results in the subdivision of the grains into smaller units or “cells” with the rearranged dislocation structures forming the grain boundaries, similar to behavior commonly seen in materials that are heavily cold-worked (i.e., mechanically deformed) in metal fabrication applications. This refining of the microstructure is often correlated to a loss of stable microstructural evolution because the increase in grain boundaries enhances the nucleation rate of fission gas bubbles and subsequent growth.

Fuel-chemical interactions

Nearly all the fuel compounds have some type of interaction with an Al matrix material and the Al alloy cladding. Under irradiation, particularly at highest powers and temperatures, this leads to the formation of distinct interaction phases that can consume a significant fraction of the Al matrix surrounding the fuel particles. For HEU dispersion fuels, with lower fuel particle density than is necessary for LEU dispersion fuels, Al matrix can accommodate a much larger fraction of the interaction phase without compromising the overall irradiation performance of the fuel at high fission density. For high-density LEU fuels, that have volumetric particle densities approaching 50%, the consumption of the Al matrix with a phase that is frequently brittle and susceptible to high rates of bubble growth can lead to an interconnection of porosity across the entire fuel zone; ultimately this phenomenon can lead to fuel failure as large voids are formed that reduce the mechanical integrity of the fuel core and inhibit heat transfer across the fuel. Images of a U-7Mo fuel before and after irradiation are shown in Fig. 4. The post irradiation microstructure shown in Fig. 4b reveals that, during irradiation, spherical fuel particles (light contrast) react with the aluminum matrix (dark contrast) to form an interaction phase (gray contrast) between the fuel and the aluminum matrix.

Research reactor fuel testing

Irradiation

As indicated previously, during the development and qualification of new fuel systems, testing to bounding conditions and beyond is conducted to ensure that the irradiation performance of the fuel meets the requirements necessary for use in research reactors. This testing establishes fuel failure limits, provides data to reactor safety analysts concerning the overall irradiation performance envelope, and generates data needed to develop and validate fuel performance codes. For the qualification of the fuel, a typical test series will encompass subsize or mini fuel specimens (miniplates) to obtain the basic irradiation performance data of the fuel material. This is followed by scaled-up fuel plate testing that is more prototypic of the actual fuel plate dimensions and is used to discern significant differences in irradiation performance in going from the smaller to larger fuel samples. Finally, the fuel is tested in a prototypic element configuration to ensure that fuel plates, mechanically constrained in an element, do not undergo unforeseen thermo-mechanical or thermal-hydraulic behavior under prototypic operating conditions.

The size of the fuel plate specimen is an important parameter in determining the test objectives. A larger quantity of miniplates can be irradiated more economically using a wider range of reactor operational parameters. Miniplates have generally been used for tests when several design and environmental variables are under investigation, when emerging fuel fabrication technologies or equipment have not yet been scaled up to prototypic size, or when a large quantity of specimens needs to be tested to suit data objectives. A schematic of a typical irradiation capsule for testing multiple miniplates in the Advanced Test Reactor (ATR) is provided in Fig. 5. Several capsules are stacked in a vertical column inside of a basket that mates to a specific reactor test position.

Fig. 4 Scanning electron microscope images of a U-7Mo fuel (a) as-fabricated and (b) following irradiation, demonstrating the formation of extensive interaction phases between the fuel and the Al matrix. The light contrast spherical features are fuel particles, dark phase is the Al matrix and the gray regions are interaction phase.

Fig. 5 Miniplate test capsule assembly containing eight plates per capsule.

Because the larger engineering-scale behaviors of fuel plates may not be readily exhibited at the miniplate scale, larger-scale tests are used to determine how performance differs with plate size. Fabrication processes necessary for larger fuel plates may result in microstructural characteristics that differ from those of miniature fuel plate, and larger specimens also provide a vehicle for determining fuel behavior and reliability for fuel specimens produced by scaled-up fabrication processes. Large-size specimens are generally irradiated in smaller quantities due to space constraints in test reactors.

After substantial data has been collected using large-size plates and miniplates prior to fuel element demonstrations to ensure a low risk of failure, plates are assembled into fuel elements for demonstration and qualification of the scaled-up fuel design. Fuel element demonstration testing requires that a repeatable pilot-scale fabrication process is in place and qualified. Element testing provides a prototypic environment for testing fuel elements that represent, as closely as possible, axial, radial, and azimuthal power shape and flow conditions of the test reactor in which the elements are being tested. Element testing for research reactor fuel is similar to a lead test assembly (LTA) used in light-water reactors to demonstrate performance of a new fuel design in a specific reactor. However, frequently when developing conversion elements to convert from HEU to LEU, it is not possible to test a developmental element in the end-use research reactor. In this case, design demonstration elements (DDE) are tested in a separate reactor that has prototypic design features but may not represent the exact dimensions of the actual fuel element. Test conditions are matched to the reactor being converted as closely as possible at the element level. Test conditions for each plate are defined by the element test environment, so it is not possible to have independent test conditions for each plate within the element.

Post-irradiation examination

PIE is conducted on fuel plates to assess the irradiation performance (as indicated in post-irradiation measurements and inspection) and generate the data needed to support fuel qualification and reactor safety analysis. PIE is typically separated into two phases; non-destructive examination (NDE) and destructive examination (DE). For NDE, fuel plates remain intact and interrogation methods include visual examination, neutron radiography, high-resolution profilometry, immersion density and scanning gamma spectroscopy. The NDE techniques are focused on quantifying the extent of bulk and local dimensional changes; the observation of any evidence of fuel failures, including formation of blisters (visual, profilometry, immersion density), pillows, or cladding delamination; the extent of cladding oxidation and initial estimation of fuel burnup and fission product distribution (scanning gamma spectroscopy). **Fig. 6** provides a representation of the measurements made during high-resolution profilometry to evaluate fuel swelling and other dimensional changes. Neutron radiography is used to evaluate whether the fuel has remained in-tact during irradiation and to identify fuel fracture, relocation, or other anomalous behavior that occurred within fuel material (the Al cladding is effectively transparent to neutrons). In combination, all these techniques are used to identify features of interest that can inform and focus subsequent DE investigations.

DE investigations are conducted to evaluate the fuel microstructure, further refine burnup measurements, obtain blister threshold temperature, and, in the case of monolithic fuel types, measure mechanical property changes of the fuel core. Samples generated during sectioning for destructive examination are also used to make thermophysical property measurements to ascertain changes in its thermal conductivity during irradiation. Because of the highly radioactive nature of irradiated fuel specimens, localized regions of the fuel plates are typically sectioned and reduced in size to perform more detailed microstructural and microchemical characterization utilizing analytical scanning and transmission electron microscopy. In this way, a picture of the microstructural changes can be mapped across length scales from bulk properties to the atomic scale, providing a detailed understanding of how fuel property degradation under irradiation impacts overall irradiation performance. During destructive exams, full sized plates are also tested to determine the blister threshold temperature. If appropriate, fuel plates are heated beyond the melting temperature to

Fig. 6 Topographic representation of an irradiated miniplate showing measured thickness changes compared to the as-fabricated measurements. Lighter yellow regions were indicative of a separation of the fuel cladding in that location. These measurements were taken on a U-10Mo monolithic plate following irradiation testing in the ATR in the United States.

evaluate release rates of fission products from the fuel. This information is critical for larger research reactors (such as the ATR) that have a significant fissile material inventory that must be addressed in safety assessments.

Introduction

The generation of energy by means of nuclear power has evolved a lot over the years since the 1950s, especially in the last few decades. It became more and more obvious, that the strategy for the management of used fuel as a major part of the waste generated in the nuclear energy programs, is a key issue mainly in view of public acceptance.

In the early phase of nuclear power production (1960s and 1970s), all used fuel was foreseen to be reprocessed. Recovered uranium and plutonium were supposed to be recycled in fast neutron reactors to avoid potential supply shortages of natural uranium. In the 1980s, some countries have decided to reprocess used fuel and recycle uranium and plutonium as so-called mixed

oxide (MOX) and Uranium Reprocessed Enriched fuels in light water reactors (during the same period, other countries have changed their strategy and implemented an open fuel cycle).

Nuclear energy systems of the future, as they were defined by the Generation IV International Forum (GIF), are supposed to provide a sustainable energy generation for the future (Kelly, 2014). The major benefits for used fuel recycling are the conservation of natural uranium resources, reduced dependence on foreign fossil fuel, the reduction of the nuclear waste radiotoxicity and the heat load of repositories. Other big challenges for the implementation are significant costs, safety and increasing proliferation concerns also affecting the public acceptance of these technologies.

The various activities associated with the production of electricity from nuclear fuels are referred to as the nuclear fuel cycle (see Fig. 1). The nuclear fuel cycle starts with the mining of uranium and ends with the disposal of nuclear waste. When opting for the reprocessing route of used fuel fissile materials will be recycled and remaining waste will be vitrified before final disposal.

The current reactors use less than 1% of the uranium available in nature. With such a low efficiency, the uranium resources identified today worldwide might last only about 100 years with the currently installed nuclear power infrastructure. Depending on the growth rate in the future use of nuclear systems, this time span could also be significantly lower. New energy systems using a technology based on the combination of fast neutron reactors with advanced multi-recycling of the fuel would improve the usage of natural uranium resources by at least a factor of 50 and possibly even higher depending on the scenarios adopted.

A comprehensive management of used nuclear fuel from the operation of nuclear power plants is a multistage process, where all steps need to be carried out in an effective, safe and responsible way. The two main management options are final disposal and reprocessing. In the first case, the so-called “open fuel cycle,” the fuel is disposed of without further treatment. In numerous research programs worldwide, involving underground laboratories in potential geological formations (granite, clay salt or volcanic rock) the long-term evolution has been investigated and the common outcome is that under normal evolution scenarios, the dose rate released to the surface is significantly lower than the natural radiation background.

The second option also called “closed fuel cycle,” involves extraction of the energetic components in the used fuel, mainly plutonium and uranium, for reuse. Consequently, in fully closed cycles based on fast reactors and adapted advanced recycling of the used fuel components by anticipated technologies, 50–100 times more energy can potentially be generated from the uranium mined originally. If at the same time a partitioning and transmutation (P&T) would be deployed, the waste could decay to low levels of radioactivity in less than 1000 years in contrast to > 100.000 years for direct disposal of used fuel. However, all of these steps involve additional dedicated up-scaled facilities, and require substantial further research and development before they would be commercially available.

Worldwide, increasing inventories of surplus plutonium are stored in the main nuclear countries, they need to be secured against the risk of diversion. In order to reduce therefore these inventories, several countries including those with accumulated surplus weapons-grade plutonium, have opted for the so-called mixed oxide MOX strategy where plutonium is used as fissile material in the civil nuclear industry. Globally MOX fuel represents today almost 5% of nuclear fuel used. In France about 10% of the

Fig. 1 The nuclear fuel cycle.

fuel in the reactor fleet is MOX. The increased proliferation risk associated with increased separation of plutonium from used fuel leads to controversial public acceptance discussions in many countries.

A common feature of all routes is the need of a more or less long-term intermediate storage of the used fuel discharged from the reactor. A thorough characterization of the fuel and its evolution during storage is essential to guarantee stability and thereby safety for often undefined storage duration. Also for the final disposal option to be implemented later, the characterization helps to understand the evolution of the waste package in the disposal site, including all kind of parameters affecting possible interactions with the corresponding geological formation. This chapter aims to give a detailed description of the key physical and chemical characteristics of fuel during irradiation, and the evolution of used nuclear fuel after irradiation and discharge from reactors. The main focus is of course on UO_2 fuel, however also the MOX fuel case will be discussed.

Nuclear fuel irradiation

Especially at the beginning of the irradiation process, when the fission event density is the highest, leading to a maximum linear power and central temperature, a significant relocation of fission products, depending on their volatility, takes place in the fuel. In fact, in an oxide fuel, temperature gradients of at least 500°C between the fuel periphery ($\sim 500^\circ\text{C}$) and the fuel center ($> 1000^\circ\text{C}$) lead to strong migration and diffusion to the fuel pellet rim. The grain structure of the fuel initially pressed from UO_2 powder, induces a precipitation of some of the fission products at the grain boundaries, noble elements partially form metallic precipitates. The most volatile elements, i.e. in addition to the fission gases xenon and krypton, mostly cesium, tellurium and rubidium partially migrate towards and outside of the fuel pellet edge where they are deposited as elements or potentially form compounds, also with the cladding material. They can also be integrated in an oxide layer formed inside the zircaloy cladding since the very beginning of irradiation. Parts of the volatiles, above all fission gases are found in the fuel rod plenum.

The irradiation process leads to the formation of numerous radionuclides by fission of ^{235}U . As irradiation goes on, more and more fissile ^{239}Pu is formed by neutron capture of ^{238}U and higher actinide isotopes are consequently formed by a cascade of neutron absorptions. At the same time the high temperature and a steadily increasing radiation field building up upon progressing irradiation is responsible for significant thermophysical modifications of the fuel (Kleykamp, 1985). In the very high temperature gradient of typically at least 500°C between the pellet center ($> 1000^\circ\text{C}$) and the pellet periphery ($\sim 500^\circ\text{C}$), many fission product elements, depending on their volatility and thermos-physical properties migrate to the colder outer regions of the fuel and exhibit totally different behaviors.

In the course of years nuclear industry has steadily increased the utilization efficiency of fuel, especially by increasing the burnup. This leads to increased radiation fields and consequently enhanced impact on fuel structure also interaction with cladding, itself supposed to be the first barrier against radioactivity release. Fig. 2 shows an exploded schematic drawing of an irradiated fuel rod segment. The different regions marked indicate locations with potential fission product and higher actinide accumulation.

The fuel pellet cracks during irradiation due to temperature gradients, being aware that micrographs made in a hot cell laboratory do not represent the fuel status at the end of irradiation because also the cool-down process induces cracking of the ceramic fuel. Volatile fission products are accumulated in the cracks and in the gap between the fuel and the cladding. Metallic and oxide precipitates are formed inside the grains of the fuel and at the grain boundaries.

Fuel composition after irradiation

Used fuel is among the most complex materials known worldwide. After irradiation nuclear fuel contains a large number of radioisotopes of most elements listed in the Mendelev table of elements (see Fig. 3).

Starting from the commonly used pure UO_2 fuel, the fission and neutron capture reactions lead upon irradiation to the formation of considerable amounts of different isotopes of elements from all eight element groups in the periodic table. Gen-II reactors were typically designed to achieve a burn-up of about 40 GWd/t. With an improved fuel technology, these same reactors are now reaching up to 60 GWd/t. The goal is to produce a given amount of energy with a lower number of fresh nuclear fuel elements and to generate less used nuclear fuel elements. Furthermore the downtime of the reactor for refueling is reduced. At some stage however, the build-up of fission product neutron poisons (mainly rare earth fission products) reach values which necessitate the reactor to be shut down and refueled.

Used fuel is a highly radioactive material and contains at an average burnup of 45 GWd/t about 94% U-238, about 1% U-235 that has not fissioned, almost 1% plutonium and 4.5% fission products with the following approximate composition: Rare Earths, Y: 24%, Ru, Tc, Rh, Pd: 16%, Kr, Xe: 15%, Zr, Nb: 14%, Mo: 13%, Cs, Rb, I, Te: 11%, Ba, Sr: 7%.

All these new chemical elements are either included in the UO_2 fluorite structure if soluble, or segregated out of the matrix in solid or gaseous forms. A detailed classification of fission products was published by Kleykamp back in 1985 (Kleykamp, 1985), as follows:

- Dissolved in the matrix: Rb, Sr, Y, Zr, Nb, Te, Cs, Ba, La, Ce, Pr, Nd, Pm, Sm, Eu
- Partly precipitated at grain boundaries (oxides): Rb, Sr, Zr, Nb, Mo, Se, Te, Cs, Ba
- Metallic precipitates: Mo, Tc, Ru, Rh, Pd, Ag, Cd, In, Sn, Sb, Se, Te
- Volatiles: Br, Kr, Rb, I, Xe, Cs, Te

Fig. 2 Schematic exploded illustration of an irradiated fuel rod segment with areas of potential fission product and actinide accumulation.

Some of these elements are in a single physical form (see list above), whereas others are present under different forms depending in a proportion influenced by the fuel temperature, the fuel oxidation state, interactions with the cladding, the fuel matrix and also the other elements formed upon irradiation.

The above mentioned burn-up has also a considerable impact on the content of transuranic elements which are formed by neutron capture of ^{238}U (see Fig. 4).

It is obvious, that also the actinide content is increased with higher burnups, if, at the same initial ^{235}U enrichment, more and more higher actinide isotopes, formed by neutron capture, are the fissile material. In Table 1 the content of transuranium actinides in LWR UOX and LWR MOX at different burnups are compared.

The Cm content is almost a factor of 10 higher if the burn-up is raised from 33 to 60 Gwd/t U. The same is true for MOX fuel where ^{239}Pu is the fissile material in comparison to an LWR fuel at the same burnup of 45 Gwd/t U.

Element redistribution upon irradiation

In discharged irradiated fuel, the above mentioned overall content inventories of fission products and actinides are not homogeneously distributed. In the strong temperature gradient as described in the previous chapter, fission products migrate to the colder fuel periphery regions. Pu and consequently minor actinides are formed by neutron capture preferentially at the fuel periphery by incident neutrons. Various experimental techniques are used to quantify the distribution of fission products and actinides. Those are mainly, scanning electron microscopy (SEM), X-ray, X-ray fluorescence (XRF) (Mogensen et al., 1999) and most commonly Electron Probe Microanalysis (EPMA) (Fisher et al., 2002; Walker et al., 1996a).

In Fig. 5, EPMA line-scans show the redistribution of 4 key elements in a UOX fuel with a burn-up of 62.8 Gwd/tHM.

The radial distribution of uranium is obviously almost constant along the whole radius of the fuel pellet. A slight decrease at the pellet periphery is due to the above mentioned conversion of uranium into plutonium by neutron capture. This observation is of course confirmed by the plutonium increase in the outer region of the fuel pellet.

The fission product neodymium is commonly regarded as good burn-up indicator, because it does not move away from its point of formation and therefore allows in the present case to determine the radial burnup variations. Its line-scan displays a quite homogeneous distribution of fission events along the pellet radius, obviously correlated with the homogeneous distribution of fissile ^{235}U in the fuel at the beginning of irradiation.

At the fuel periphery the neodymium content increases exponentially, due to the fact that as the irradiation process goes on, more and more ^{239}Pu formed through neutron capture of ^{238}U replaces ^{235}U as the fissile material (see Fig. 6).

**Fig. 5** EPMA line-scans for U, Pu, Cs and Nd of a UO_2 fuel at 62.8 GWd/tHM burnup.

Cesium is a major fission product with a high volatility at temperatures exceeding 1000 °C and thus a high mobility towards the colder fuel periphery. The large increase in the outer part of the fuel pellet are due to the fission of fissile plutonium in this region. Gamma scans of entire fuel rods show increasing accumulation of cesium at the pellet-pellet interface at high fuel burn-up (Walker, 1997). The fission gases xenon and krypton have a migration behavior similar to cesium (Manzel and Walker, 2002; Lassmann et al., 1995; Nogita and Une, 1995).

The above findings mean, that in case of a failure of the fuel rod during storage or disposal, e.g. a defect in the cladding, the pellet rim zone will be the first in contact with the environment and the inventories present in this zone will determine the immediate release to the biosphere, the so-called instant release fraction (IFR).

Nuclear fuel restructuring

Using SEM and EPMA, Manzel and Walker have thoroughly investigated the distribution of used fuel constituents in connection with microstructure changes, such as significant recrystallization processes especially in the rim zone, for fuels with high burnups up to 100 GWd/t (Walker et al., 1996a; Walker, 1997) and in the plutonium rich particles of MOX fuel (Fig. 7).

At about 50 GWd/tHM the UO_2 grains in the outer region of the fuel pellet begin to recrystallize due to accumulation of irradiation damage, leading to an increase in fission gas release to the rod free volume (Lassmann et al., 1995; Nogita and Une, 1995). The transformed microstructure, also called high burnup structure (HBS), consists of small grains of average size 0.15 μm and a high concentration of pores of typical diameter 1–2 μm (Spino et al., 1996; Ray et al., 1997; Xiao and Long, 2016). As the burn-up increases the grain subdivision progresses towards the center of the fuel and further grain subdivision in the outer pellet zone is observed (Wiss and Rondinella, 2010; Walker et al., 1997; Ronchi et al., 2004; Sari et al., 1979). Two mechanisms of formation

Fig. 6 Content of main uranium and plutonium isotopes in nuclear fuel at increasing burnup.

for the HBS structure. Spino et al. assume that migration of fission gas out of the UO_2 lattice induce the formation of faceted gas pores, overpressurisation of the pores and grain sub-division around the pores due to the local build-up of mechanical stress (Spino et al., 1998). Nogita and Une (Nogita and Une, 1995) postulate, that the accumulation of irradiation damage leads to the formation of dislocation tangles, with increasing burnup these unravel to produce sub-divided grains and those with high-angle boundaries act as nuclei for recrystallisation.

MOX fuel often produced as master-mix by comilling processes such as OCOM or MIMAS (Staicu et al., 2011). Pu agglomerates up to 200 μm in size are dispersed in a matrix of natural or depleted UO_2 . For LWR, the plutonium content in the agglomerates often ranges between 6% and 10%. During irradiation to a normal burn-up of ~ 45 GWd/tHM, about 75% of the fissions occur in the Pu-rich agglomerates (calculation based on data from Lassmann et al., 1995), leading to a high local burnup in the agglomerates, up to 270 GWd/tHM (Walker et al., 1996b; Bailly et al., 1999). This results after irradiation in a microstructure of fine grains and large pores with a diameter of several microns, similar to the high burn-up structure (HBS) formed at the periphery (rim) of UO_2 pellets with local burnup above 60 GWd/tHM (Govers et al., 2019).

Fission gas behavior

The increased fission at the pellet periphery must also be the origin of the high fission gas released to the rod free volume. The release mechanisms and pathways for volatile fission products is not fully clear. Puncturing of PWR rods in the burn-up range of 15–100 GWd/tHM shows that up to 50 GWd/tHM only 5–6% fission gas is released (see Fig. 8).

With increase in burnup from 50 to 100 GWd/t the percentage of fission gas released to the rod free volume increases exponentially to about 25%. This finding goes along with a significant restructuring of the fuel across the pellet radius, but mainly at the pellet periphery (see Fig. 2). It is quite obvious, that, because as burnup progresses more and more fission events occur in the outer pellet rim, where the actual process of recrystallisation leads to gas release from the fuel. Nogita and Une (Nogita and Une, 1995) have shown that prior to recrystallisation, the fuel grains contain a high density of nanometer size gas bubbles, which are absent after grain sub-division has occurred. Bremier et al. (2000a) have calculated that at the temperature of the pellet rim (400 °C), radiation-enhanced diffusion results in the release of large fractions of fission gas from the recrystallised grains. At the same time, they found (Bremier et al., 2000b) that for an un-recrystallised grain of diameter 10 μm , it requires 572 days to obtain a fractional release of 0.01 using an apparent diffusion coefficient of $1023 \text{ m}^2/\text{s}$. This is the diffusion coefficient that gives the equilibrium xenon concentration of 0.2–0.3 wt% measured by EPMA in the grains of the high burn-up structure (Nogita and Une, 1995).

Fig. 7 Restructuring of nuclear fuel upon irradiation showing high burn-up zones at the pellet periphery for LWR UO₂ fuel and in the plutonium-rich agglomerates for LWR-MOX fuel.

Fig. 8 Fission gas release to the fuel rod plenum as a function of burnup.

Aging mechanisms of used fuel

Aging processes occurring during storage of used nuclear fuel rods are safety-relevant both for storage and for handling/transportation processes. In particular, it is important to assess all mechanisms that may cause severe degradation of the mechanical integrity of the used fuel rods, mainly affected by helium gas buildup, dislocations, grain disintegration, hardness, heat capacity, swelling, and microstructural changes of the spent fuel matrix. Such mechanisms are strongly affected by the radioactive decay power generated in used fuel, which determines also the temperature level experienced by the rods in the dry storage container. The build-up of alpha-decay damage and helium may become a determining factor in the evolution of the mechanical properties of the used fuel (Bruno et al., 2007; He et al., 2007).

Hydrogen formed by corrosion of zircaloy cladding of the fuel rods, is dissolved or precipitated as hydrides in the metal matrix and affects the status of the cladding. Nevertheless, the experience of more than 40 years of wet storage of several million light water reactor rods shows that used nuclear fuel with zirconium alloy cladding have excellent durability (IAEA, 2006). Destructive and nondestructive examinations of PWR Zircaloy-clad rods showed no detectable changes in the cladding characteristics after 20–30 years of wet storage. Indicative techniques show that corrosion rates in wet storage should be <0.007 mm/year. The cladding also retained significant creep ductility after dry storage.

Composition evolution with time

After irradiation, the elemental and chemical composition changes of the fuel are only minor. On the other hand the radioactivity emitted from the fuel changes by orders of magnitude over the repository timescale. Fig. 9 shows the evolution of the total α - and β -activity of a PWR fuel at 40 GWd/tHM over a storage time up to 1 million years.

The main difference between discharged UOX and MOX fuel is that the total α -activity in the MOX is nearly 7 times larger, this factor decreases to 3 after 100,000 years. The fact that α -particles are emitted by quantum tunneling out of the nucleus with extremely low probabilities and decrease with the particle, low-energy α -emitters are generally much more long-lived than $\beta(\gamma)$ -emitters (Krane, 1988).

The very intense $\beta(\gamma)$ -field emitted by discharged fuel is due to the decay of mainly the short-lived radionuclides, listed in Fig. 10, where also the decay curves of individual isotopes of light (left) and heavy (right) fission products present in a UO_2 fuel with a burnup of 40 GWd/tHM after 1 year cooling are shown.

Most of the fission product isotopes listed in Fig. 10 decay between 1 and 600 years, except ^{99}Tc , ^{99}Tc , ^{79}Se , ^{93}Zr , ^{94}Nb , ^{107}Pd , ^{126}Sn , ^{129}I and ^{135}Cs . This is well in agreement with the evolution of the total $\beta(\gamma)$ activity in Fig. 9.

Fig. 9 Evolution of the total α - and β -activity of a PWR fuel at 40 GWd/tHM over a storage time up to 1 million years.

Fig. 10 Decay of lighter (left) and heavy (right) fission products present in a UO_2 fuel with a burn-up of 40 Gwd/tHM after 1 year cooling as a function of storage time.

Radiation damage

Alpha radiation has a typical kinetic energy of about 5 MeV. It can heavily ionize matter and quickly deposit its energy along the short paths. Defects created by displacement cascades preferentially at the fuel periphery are extensively recombined in UO_2 and PuO_2 and hence, no matrix amorphization can be detected in those materials (Matzke, 1982; Van Brutzel et al., 2006). Nevertheless, lattice parameter increase caused by α -radiation damage that displaces atoms in the lattice can lead to microscopic swelling, which is accommodated by the free space between fuel and cladding. Radiogenic helium and alpha-damage can cause early material degradation and enhanced corrosion (Roudil et al., 2004; Fanghaenel et al., 2013; Poinssot et al., 2005).

The β -decay results in formation of elements of different valence state and eventually change the oxidation state of the UO_2 matrix. Matzke et al. could demonstrate that in high burnup UO_2 fuel the oxygen potential in the fuel appears to be controlled by molybdenum (Mo/MoO_2). Mo is among the most abundant light fission product in used fuel (Matzke, 1982).

Many studies were carried out also on tailored specimen to study individual effects. The question how particles from radioactive decay interact with matter was already investigated by the nuclear pioneers M. Curie, J. Thomson, N. Bohr and E. Rutherford (Curie, 1900; Rutherford et al., 1899). The development of ion accelerators allowed extensive studies on radiation damage in all types of materials. Linked to the use of the Monte Carlo code Stopping and Range of Ions in Matter (SRIM) for the estimation of energy loss, range, and damage, the description of the main processes of particles/ions interactions with matter is given (Ziegler et al., 1985).

The equivalent damage is indicated as displacements per atoms (dpa). The investigation of alpha-damage by XRD, TEM and Vickers Hardness showed that the fluorite structure is preserved but with a substantial increase in lattice parameter (up to 0.6%), the formation of dislocation loops (41022 m^3), the formation of helium bubbles and an increase of the Vickers Hardness. For instance annealing studies performed on UO_2 specimen doped with alpha-emitters, show that recovery of the lattice parameter is complete at 1100 K, with the major recovery occurring between 600 and 900 K. (Matzke, 1995).

The special case of SUPERFACT fuel

The SUPERFACT experiment carried as a collaboration project of the French Commissariats à l'Énergie Atomique (CEA) and the European TransUranium Institut (TUI) aimed to study the transmutation of MA's (Walker and Nicolaou, 1995). Several fuels with neptunium and americium contents from 2 to 45 wt were irradiated for 365 electric full power days (EFPD) in the French PHENIX reactor (FR). Post-irradiation examinations, carried in the CEA and TUI hot cell laboratories to assess the transmutation efficiency include in 1991 SEM examinations. Two samples of a fuel with the composition $\text{U}_{0.6}\text{Am}_{0.2}\text{Np}_{0.2}\text{O}_2$ taken at the same radial positions were again examined after 12 years of storage in the hot cell laboratory. Calculations show that the α -dose accumulated after this time period is equivalent to MOX (9% Pu, 50 Gwd/tHM) after 400,000 years storage. The SEM micrographs recorded in 1991 and 2003 are compared in Fig. 11.

Even if of course the samples selected are not identical, but taken at adjacent axial positions, it is obvious that at a magnification of $2000\times$, no difference is visible despite the huge α -dose rate deposited during 12 years of storage.

Also international programs aiming at investigating the technical bases to ensure safe, long-term used fuel storage and future transportability. In the United States, the Electric Power Research Institute (EPRI) has launched the so-called Extended Storage Collaboration Program (ESCP) with the participation of 70 industry, governmental, and academic organizations from at present

Fig. 11 Evolution of the total α - and β -activity of a PWR fuel at 40 Gwd/tHM over a storage time up to 1 million years.

20 countries to identify research gaps to allow interim storage of used fuel up to 100 years. A major partner is Germany, where the final disposal project Gorleben has been given up, safe long intermediate storage has to be implemented. Also in Belgium, post-irradiation examinations (PIEs) of spent BWR-MOX and PWR-UO₂ fuel rods irradiated in commercial LWRs and stored for 20 years were carried out to evaluate fuel integrity during storage no marked difference in the visual inspection, fission gas release, oxide layer thickness, pellet microstructure, and cladding mechanical properties or hydride orientation after storage (Sasahara and Matsumura, 2008).

Conclusions

The irradiation of nuclear fuel results in an extremely complex material. A strong temperature gradient of ~ 500 °C between the center and fuel periphery leads especially for volatile fission products to an accumulation at the fuel pellet interface, neutron capture is responsible for large quantities of transuranium actinides at the fuel periphery. Strong $\beta(\gamma)$ - and α -radiation fields forms defects and dislocations, however also due to high temperatures an almost complete healing of these defects is observed. Some studies claim, that during storage the much lower temperatures, alpha-damage defects (dislocation loops) could lead to microcracking, starting from 1000 years after discharge especially in MOX fuel with higher α -radiation. The consequence could be on the long term a partial loss of integrity. However the Superfact fuel indicates, that even extremely large α -radiation energy deposits, equivalent to those of MOX for very long storage times (even longer for UO₂), does not give evidence for any disintegration process.

Commercial spent nuclear fuel (CSNF) locations and amounts

International Atomic Energy Agency (IAEA) member countries regularly report the amount of spent fuel in their country including the type(s) of storage systems used in their countries. The most recent set of reports are included in the proceedings of the *Sixth Review Meeting of the Contracting Parties to the Joint Convention on the Safety of Spent Fuel Management and on the Safety of Radioactive Waste Management*, Vienna: International Atomic Energy Agency (2018), available at: <https://www.iaea.org/topics/nuclear-safety-conventions/joint-convention-safety-spent-fuel-management-and-safety-radioactive-waste/documents>.

As of December 31, 2013, the IAEA reported that a total of roughly 370,000 metric tons of uranium (MTU) of spent fuel (commercial SNF and from other sources) was generated (IAEA, 2018). This is summarized in Table 1.

Characteristics of CSNF requiring management during storage, transportation, reprocessing, and disposal

The primary characteristics of CSNF that require safe management are the high levels of radiation and decay heat.

When fresh uranium fuel is placed in a reactor, it typically contains 3–5% U-235 and 95–97% U-238. When it is removed, it contains about 0.7–1% U-235, 93–96% U-238, 1% plutonium, 0.1% minor actinides (e.g., Np-237, Am-241, Cm-244), and 4–5% fission products as shown in Fig. 1. Some of the fission products are long lived, such as I-129 and Tc-99, while others have shorter half-lives.

The primary contributors to both radiation and decay heat during the first few decades of storage are the fission products Cs-137 and Sr-90—both of which have half-lives of approximately 30 years. Both decay heat and the radionuclides decrease with time—an example of which is shown in Fig. 2. The exact inventory of radionuclides and decay heat generation versus time is a function of the burnup of the CSNF: the amount of energy generated per unit mass of the initial uranium in the fresh fuel (expressed in gigawatt-days per metric ton of uranium (GWd/MTU)). Thus, CSNF storage systems must be able to shield from the intense radiation and remove the decay heat during the storage period.

Commercial spent nuclear fuel storage systems

Today, the majority of CSNF generated in water reactors is stored in spent fuel pools (SFPs) adjacent to operating reactors. This general type of storage is called “wet” storage. Two examples of SFPs are shown in Fig. 3.

Due to the absence of operational geological repository or reprocessing (in most countries) for CSNF, many of the SFPs are currently nearing or are at capacity in countries where no reprocessing-recycling is implemented. In such a situation, some CSNF must be removed from the pool and stored elsewhere in order to continue to operate the reactors. Some countries, such as Sweden, have built additional SFPs at locations away from the reactors. The SFP in Sweden has been designed with sufficient capacity to store 100% of the CSNF anticipated to be generated in that country.

There is an increasing use of “dry” storage systems in which the water is and replaced by an inert gas. Individual dry storage systems are capable of storing a few up to several tens of CSNF assemblies. There are two types of such dry storage systems. One employs a set of bolted metal lids, commonly referred to as “casks,” such as those shown in Figs. 4 and 5. The other employs a welded steel “canister” with welded lids inside a concrete “overpack,” such as those shown in Figs. 7 and 8. Most recent casks/canisters are often designed for both storage and transportation, so they are called “dual-purpose casks” (DPCs). However, many of the used casks and canisters were single-use designed for storage, creating a long-term burden associated to the need

Table 1 Spent fuel discharged from nuclear power plants (MTU), as of December 31, 2013.

Fig. 1 Composition of spent nuclear fuel after 10 years of cooling. Figure 6 from BRC (2012) *Blue Ribbon Commission on America's Nuclear Future—Report to the Secretary of Energy*. Washington, DC: Blue Ribbon Commission on America's Nuclear Future.

for initially transporting the CSNF and repackaging it. At some locations for which the reactor and associated buildings have been decommissioned, there is no longer a SFP available if it is necessary to reopen the cask or canister for some reason. Furthermore if there is no other place for the CSNF to be transported, then the all that will remain is the CSNF in storage and the site cannot be fully decommissioned.

Cask systems use a double lid design, such as shown in Fig. 6. Each lid uses two O-ring gaskets to ensure the lid provides an adequate seal to limit the release of gas inside the cask body where the CSNF is placed.

The loading procedure for the bolted metal lid cask design is as follows. The empty cask with the lid removed is lowered into the SFP, and the CSNF is loaded into individual storage cells. The cask containing the CSNF is then lifted still almost entirely full of water into a handling bay next to the SFP, and the primary lid that has two O-rings for the seal is emplaced and bolted down. Next, the majority of the water is drained out of the cask interior via a drain orifice. A vacuum is created through the vent orifice to remove remaining water inside the cask via vaporization, after which the cask interior is filled with an inert gas, such as helium. Then a small lid covering the drain orifice is bolted down. The secondary lid is then emplaced over the primary lid again using a double O-ring design. A helium overpressure system is then installed that provides a positive pressure between the two seals in both lids. Maintaining a pressure between the seals that is greater than the pressure inside the cask ensures that if there is a loss of seal, no gas from inside the cask in which the CSNF is stored can escape into the environment. A protective cover is then emplaced, and the cask is transferred onto the concrete storage pad.

The bolted metal systems provide the safety functions via the cask body, seals, and lids. The safety functions include shielding, heat transfer, confinement subcriticality, and structural integrity. Decay heat is transferred through the cask body via metal cooling fins. The cask body, primary, and secondary lids provide gamma and neutron shielding. The pressure between the two seals is

Fig. 3 Examples of spent fuel pools (SFPs) adjacent to reactors. CSNF is discharged from the reactors into these SFPs. The bottom figure shows a spent nuclear fuel assembly being loaded into a storage cell in the spent fuel pool.

Fig. 4 CASTOR V/19 bolted metal storage cask. Courtesy of GNS at <http://www.gns.de/language=en/21551/castor-v-19>

continuously monitored during the entire time the cask is in use. Structural integrity includes loss of cask confinement or shielding due to seismic and atmospheric events that could cause the cask to tip over or to be impacted by projectiles. As will be discussed later, the primary barrier preventing loss of gas or particulates from inside or and the intrusion of air or water into the cask is the double O-ring seal design. Hence, the long-term integrity of the seals is important to maintaining confinement during the entire storage period.

The second type of dry storage system that holds up to a few tens of CSNF assemblies uses welded steel “canisters” inside a concrete “overpack,” such as those shown in [Figs. 7 and 8](#). As opposed to the bolted metal systems that provide the safety functions using the cask itself—along with the seals and lids—the safety functions are partially divided between the canister and the concrete overpack. The welded canister provides the decay heat removal to the outside of the canister, confinement and subcriticality safety functions, and also contributes to the overall structural integrity of the system; the concrete overpack provides the primary structural and shielding functions, and is also designed to transfer the heat from the canister via natural air convection within the air gap between the outer canister wall and the inner concrete overpack wall. For those welded canister systems stored outdoors, the concrete overpack also provides protection from rain and projectiles. [Fig. 7](#) shows the NUHOMS type of system. The NUHOMS systems are designed to store PWR and BWR CSNF assemblies horizontally. Its main components include the stainless steel canister with an internal fuel basket, and a concrete “overpack” that protects the canister and provides radiological shielding. The right image in [Fig. 7](#) is a cutaway view of the canister showing the CSNF assembly storage cells and the two lids. The left image shows the on-site transfer cask with the welded canister inside being mated up to the front of the horizontal concrete overpack just before transfer of the canister into the concrete overpack. One of the air inlet vents with a screen is shown underneath the concrete overpack entry point. There are air outlet vents located on the top of the concrete overpack to provide cooling via natural air convection.

The loading procedure for the NUHOMS type of system is as follows. With both the canister and transfer overpack oriented in the vertical direction, the empty canister without the lids is placed inside an on-site “transfer” overpack. The transfer overpack

Fig. 8 Cross section of the Holtec MPC-37 Overpack with MPC. From <https://i2.wp.com/holtecinternational.com/wp-content/uploads/2011/06/3-hi-storm-fw.jpg?w=1200&ssl=1> on 22 March 2021.

provides shielding and protection to the canister during on-site loading and handling operations and is used to transport the loaded canister to the concrete overpack. The inner diameter of the transfer overpack is slightly larger than the outer diameter of the canister. The empty canister and transfer overpack are placed into the SFP and the CSNF assemblies are placed into the individual assembly storage cells inside the canister. The canister and transfer cask are then lifted out of the SFP into an adjacent handling bay. The water is partially drained out of the canister via a drain port and the inner lid is then welded onto the top of the canister. The remaining water is then removed from inside the canister through the drain port, and a drain port cover is then welded on. An inert gas is

injected via a similar type of vent port design described for the bolted metal lid cask design above. The outer lid is then welded onto the canister. The canister and transfer cask are then placed onto the transfer trailer and lowered into a horizontal position. The transfer trailer is then moved to in front of the horizontal concrete overpack, and a hydraulic ram system is used to push the canister out of the transfer overpack directly into the concrete overpack. A shielding and structural lid is then placed on the front of the concrete overpack.

Fig. 8 is an example of a vertically oriented welded steel canister inside a concrete overpack. The loading and on-site transfer procedure for the vertical designs is the same as for the NUHOMS design except that the transfer cask and canister are always kept in the vertical position. The transfer cask with the canister are mated to the top of the open concrete overpack, and the canister is lowered into the concrete overpack, the transfer overpack is removed, and the concrete overpack lid is then installed. The concrete overpack air inlet and outlet vents are connected to the gap between the outside of the canister and the inside of the overpack to provide decay heat removal via natural air convection.

Vaults in which CSNF is stored dry in canisters is a second option that is sometimes used. An example of a vault design is shown in Fig. 9. This vault contains CSNF from the decommissioned Fort Saint Vrain high-temperature gas-cooled reactor. The right photo in Fig. 9 shows the shield plugs on top of the filled drywells.

Dry storage licensing and design criteria

General safety functions

In most countries the common safety functions that must be maintained for storage and transportation are: sub-criticality; confinement; shielding; structural integrity; thermal evacuation; and CSNF retrievability at the end of the storage phase.

Subcriticality: subcriticality can be maintained using a variety of design and operational choices, including one or more of the following:

- Ensuring no water can enter the casks or canisters for the dry storage and transportation systems;
- Including neutron poison material in the cask or canister storage cells;
- Maintaining a sub-critical geometry even if the cask or canister is full of water; or
- Ensure the CSNF placed in the cask or canister has sufficiently high burnup at a given initial enrichment.

Confinement (Confinement is required for the entire period of storage and transportation. For geologic disposal, confinement is required for only the period for which retrievability must be maintained: the first few decades to centuries after emplacement.): prevent any radioactive gases or particulates that may be inside the cask or canister from escaping into the environment, using design and operational strategies that include one or more of the following:

- Casks:
 - Use of gaskets (O-rings) to reduce the rate of gas leakage out of the cask to near zero;
 - Maintain a helium gas overpressure between the O-rings and continuously monitor for loss of overpressure;
 - Minimize bolt loosening during storage due to, for example, bolt creep or corrosion
- Welded steel canisters:
 - For austenitic stainless steel canisters:
 - Use of approved body and closure lid welding techniques to minimize the risk of a through-wall crevice or crack;
 - Minimize the likelihood that a stable crack or crevice forms;
 - Minimize the crack or crevice growth rate such that a through-wall crack will not develop during the storage or transportation period;

Fig. 9 US Department of Energy CSNF vault containing CSNF from the decommissioned Fort St. Vrain reactor in the US; vault exterior view (left) and interior charge face (right) (Hain, 2010). DOE (2009): downloaded from <http://www.nwtrb.gov/meetings/2010/june/hain.pdf> (20 March 2016).

- o For carbon steel canisters: canister body and lids are of sufficient thickness to avoid loss of wall thickness due to general corrosion during the storage or transportation period.

Shielding: maintain adequate shielding for normal, off-normal, and accident events during storage, transportation, and disposal at earlier times:

- Casks: minimize shrinkage or loss of the neutron absorber material
- Canisters in storage inside concrete overpacks:
 - o Avoid concrete overpack concrete spalling due to freeze-thaw, or corrosion of embedded rebar;
 - o Avoid development of through-wall cracks of sufficient size to allow radiation streaming.

Structural: ensure the cask or canister/concrete overpack remain sealed in the event of cask or canister/overpack tipover, seismic vibrations, or severe wind-borne missiles:

- Casks (storage and transportation):
 - o For carbon steel casks: cask body and lids are of sufficient thickness to avoid loss of wall thickness due to general corrosion;
 - o Minimize bolt loosening during storage due to, for example, bolt creep or corrosion;
- Concrete overpacks during storage:
 - o Minimize silica-alkali reaction rates;
 - o Minimize concrete rebar corrosion;
 - o Minimize concrete dry-out due to decay heat and low atmospheric humidity.

Thermal: ensure adequate decay heat removal for normal, off-normal, and accident events such that the storage and transportation—including the CSNF—do not lose any of the other required safety functions:

- Casks: ensure continuity of the decay heat removal path through the canister and embedded cask steel;
- Canisters/overpacks (storage): ensure air inlet and outlet vents in the overpack do not become blocked.

In addition, some regulations include a requirement that the CSNF in the storage systems should not suffer “gross failures” due to loss of fuel cladding integrity during storage. If the cladding is already known to have a breach at the time of loading, a special “can” or “bottle” is used to contain potential loss of particulates during storage and subsequent transportation. Since the CSNF cannot be examined once it is sealed inside the cask or canister, experimental data in conjunction with in-reactor irradiation history information is used to predict CSNF integrity.

Regulatory standards

The basis for many regulations governing CSNF storage is the IAEA Specific Safety Requirement SSR-4 (IAEA, 2017). The example of a country-specific set of CSNF storage regulations is that from the USA. The US Nuclear Regulatory Commission (NRC) licenses storage of SNF in dry storage systems and in pools (other than onsite reactor spent nuclear fuel pools) under the regulation of 10 Code of Federal Regulation (CFR) 72, “Licensing Requirements for the Storage of Spent Nuclear Fuel and High-Level Radioactive Waste.” Under Part 72, applicants can pursue a site-specific license or a general license. The regulations for a site-specific license govern both at-reactor ISFSIs and away-from-reactor storage facilities. As required in 10 CFR 72.212, to use casks under a general license, the applicant must demonstrate that the conditions in the casks’ Certificates of Compliance (CoCs) are met and that the site design, site-specific environmental conditions, and Design Basis Accidents (DBAs) including natural phenomena are bounded by the terms of the general license. In cases where the design conditions fall outside the design envelope of the cask CoC, such as high seismic areas, a site-specific license is needed. The initial licenses granted under 10 CFR 72.42 (a) were limited to 20 years. However, effective May 17, 2011, 10 CFR 72.42(a) was officially changed to allow an initial license period of up to 40 years and license extensions of up to 40 years.

Standard review plans

The NRC conducts its review of CSNF storage applications under two review plans: NUREG-1536, “Standard Review Plan for Dry Cask Storage System” (NRC, 2010) for dry storage systems and NUREG-1567, “Standard Review Plan for Spent Fuel Storage Facilities” (NRC, 2000) for storage facilities. NUREG-1927, “Standard Review Plan for Renewal of Spent Fuel Dry Cask Storage System Licenses and Certificates of Compliance” (NRC, 2016) is a review plan for renewal of ISFSI licenses and DCSS CoCs. These standard review plans are officially provided for NRC reviewers of storage license applications. However, it is common for the applicants themselves to closely follow the format laid out in these plans in the applicants’ Safety Analysis Reports (SARs) submitted with a storage license application.

Regulatory guides

Regulatory Guides provide guidance to licensees and applicants on how to implement specific parts of NRC regulations, techniques used by NRC staff to evaluate specific problems, and data needed by NRC staff in its review of applications. Regulatory Guides are reviewed about every 10 years. The Regulatory Guides applicable to dry storage are found in the Fuels and Materials Facilities

(Division 3) section found at <https://www.nrc.gov/reading-rm/doc-collections/reg-guides/fuels-materials/rg/>. The following is a listing of select Regulatory Guides with brief descriptions relevant to extended dry storage:

- Regulatory Guide 3.48, “Standard Format and Content for the Safety Analysis Report for an Independent Spent Fuel Storage Installation or Monitored Retrievable Storage Installation (Dry Storage).”
- Regulatory Guide 3.50, “Standard Format and Content for a License Application to Store Spent Fuel and High-Level Radioactive Waste.”
- Regulatory Guide 3.54, “Spent Fuel Heat Generation in an Independent Spent Fuel Storage Installation.” This revision provides an updated methodology for determining heat generation rates for PWR and BWR fuel with greater flexibility. The scope of the previous revision was restricted to PWR fuel with a maximum burnup of 50 GWd/MTU and BWR SNF with a maximum burnup of 45 GWd/MTU. This revision allows the loading of higher burnup SNF by using more accurate methods for calculating decay heat and covering a wider range of fuel characteristics and operating history.
- Regulatory Guide 3.60, “Design of an Independent Spent Fuel Storage Installation (Dry Storage).”
- Regulatory Guide 3.61, “Standard Format and Content for a Topical Safety Analysis Report for a Spent Fuel Dry Storage Cask.” The NRC recommends revising this Regulatory Guide due to outdated guidance.
- Regulatory Guide 3.62, “Standard Format and Content for the Safety Analysis Report for Onsite Storage of Spent Fuel Storage Casks.” The NRC recommends revising this Regulatory Guide due to outdated guidance.
- Regulatory Guide 3.72, “Guidance for Implementation of 10 CFR 72.48, Changes, Tests, and Experiments.”
- Regulatory Guide 3.73, “Site Evaluations and Design Earthquake Ground Motion for Dry Cask Independent Spent Fuel Storage and Monitored Retrievable Storage Installations.”

The need for longer-term storage

Due to decades of delays in the availability of geologic disposal in almost all countries, dry storage systems and the SNF contained therein must maintain their safety functions for longer than originally anticipated. Understanding the longer-term behavior of the SNF and the dry storage systems is now an active area of both R&D and licensing. The licensees of existing storage systems must demonstrate that the dry storage systems will continue to comply with the relevant regulations over longer term. If the dry storage system is often licensed for transportation, as well, then it is important that any degradation be considered for its effect on meeting transportation regulations. The regulators in some countries are requiring inspections of the storage systems prior to granting license renewals. Long-term degradation mechanisms include, but are not limited to: failure of the SNF cladding due to creep or embrittlement, corrosion of the steel canister containing the SNF or corrosion or degradation of radiation shielding such as polymeric neutron shielding and concrete neutron and gamma shielding. As of the end of 2019, no failures of dry storage systems have occurred. However, since disposal in some countries may not become available until near or beyond the end of this century, many of the storage systems will need to continue performing their safety functions for decades to come.

Glossary

Advanced gas cooled reactor (AGR) UK reactor type.

BUTEX UK process for reprocessing based on dibutyl carbitol as the extractant.

Carbon, hydrogen, oxygen, nitrogen (CHON) Principle for decomposable organic agents added to processes.

Co-extraction of actinides (COEX™) French process for co-processing U and Pu.

Commercial spent nuclear fuel (CSNF) Irradiated fuel from power reactors, also referred to as used nuclear fuel.

Critical aqueous concentration (CAC) Point at which a third phase forms based on species concentration in the aqueous phase.

Decontamination factor (DF) Ratio of an impurity in a feed compared with a product.

Dibutyl phosphate (DBP) TBP degradation product.

Dissolver off gas (DOG) Aerial effluent from dissolution process.

Distribution ratio of species X (D_X) Ratio of concentration of species X in organic phase to concentration in the aqueous phase (usually at O/A of 1).

High efficiency particulate (HEPA) Filter used to remove particles from aerial effluents.

Highly active (HA) Containing very radioactive and heat generating fission products.

Hydrogenated tetrapropylene (TPH) Industrial diluent for the extractant used as the organic phase in reprocessing.

Insoluble fission product (IFP) Isotopes produced by nuclear fission that do not dissolve in nitric acid.

Light water reactor (LWR) Generic description for thermal reactors with H₂O coolant.

Limiting organic concentration (LOC) Point at which a third phase forms based on species concentration in the organic phase.

Mixed oxide (MOx) Usually referring to (U, Pu)O₂ fuels.

Monobutyl phosphate (MBP) TBP degradation product.

Nitrogen oxide gases (NOX) Generic term for gases containing nitrogen and oxygen atoms, primarily NO and NO₂.

Odourless kerosene (OK) Industrial diluent for the extractant used as the organic phase in reprocessing.

Organic to aqueous flow ratio (O/A) Ratio of flowrates in the SX process.

Plutonium purification (PP) A solvent extraction cycle in a reprocessing plant.

Plutonium Uranium Reduction EXtraction (PUREX) Process used in commercial scale reprocessing.

Reduction oxidation process (REDOX) Process for reprocessing based on methyl isobutyl ketone.

Research and development (R&D) Scientific research and technology development.

Solvent extraction (SX) Chemical separation method also referred to as liquid-liquid extraction.

Spent nuclear fuel (SNF) Irradiated fuel, also referred to as used nuclear fuel.

Thermal denitration (TDN) A route for conversion of uranyl nitrate to uranium oxide.

Tri-*n*-butylphosphate (TBP) Extractant used in the PUREX process.

Uranium oxide (UO_x) Nuclear fuel material.

Uranium purification (UP) A solvent extraction cycle in a reprocessing plant.

Introduction

The use of nuclear energy inevitably leads to the generation of used (or “spent”) nuclear fuel. This commercial spent nuclear fuel (CSNF) can either be interim stored before direct disposal in a geological repository (the “open” fuel cycle) or recycled into new fuel for reactors (the “closed” fuel cycle). There are different degrees of recycling possible, leading to variations of the closed fuel cycle, but to date industrial scale implementation has been limited to recycle of uranium (U) and plutonium (Pu) by hydrometallurgical processes (McKay et al., 1990; Wilson, 1996; Lecomte, 2008; Nash and Lumetta, 2011; Taylor, 2015).

Typically, ~97% of CSNF can be recovered and recycled into new fuels; this process, known as reprocessing, has been widely used over the last ~60 years to recover the major reusable actinide elements: U and Pu. However, with concerns around Pu proliferation, the near-term costs of reprocessing by comparison with interim storage (where most of costs are delayed to the longer term) and the wastes generated (Cashmore et al., 2011; Poinssot et al., 2015; Williams, 2015), reprocessing at the commercial scale is currently only undertaken in a small number of countries (WNA, 2018). In conjunction with a lack of progress on geological repositories, this has led to the situation where there is about 266,000 t (te) of SNF in stores around the world (2015 figures), a figure that could rise to about 570,000 t by 2050 (Liu et al., 2005; IAEA, 2016). Eventually, decisions on SNF disposition must be taken and these stored fuels must be either reprocessed or disposed of in geological repositories designed for high-level radioactive wastes (EASAC, 2014).

Currently, nuclear fuel reprocessing at the commercial scale uses the PUREX (Plutonium Uranium Reduction EXtraction) process to recover U and Pu products (Lanham and Runion, 1949). First developed in the United States in the late 1940s, this is a hydrometallurgical process in which SNF is initially dissolved in refluxing nitric acid and then solvent extraction (SX) is used to extract U and Pu from a nitric acid solution containing the fission products into a kerosene diluent containing the extractant tri-*n*-butyl phosphate (TBP) (McKay et al., 1990; Denniss and Jeapes, 1996; Herbst et al., 2011). Separation of U from Pu is then achieved by manipulation of the Pu oxidation state and/or nitric acid concentration (Miles, 1990). Further SX cycles can be used to purify the separate U and Pu products before they are converted to solid oxides (Patterson and Parkes, 1996). The quite remarkable properties of TBP and success of the PUREX process are indicated by the fact that even now it remains almost unchallenged as the process of choice for CSNF reprocessing (Herbst et al., 2011; Netter, 2012; Nash and Nilsson, 2015).

This article provides an overview of the chemical basis to nuclear fuel reprocessing by the PUREX process focusing on the dissolution of CSNF and the separation (SX) process that generates pure U and Pu products. How the chemical separation process has been upscaled to industrial scales will be discussed with reference to second and third generation reprocessing plants operated at the Sellafield site in the United Kingdom. The Magnox Reprocessing Plant was commissioned in 1964 to reprocess uranium metal fuels from the UK’s Magnox reactors. The Thorp plant, (1994–2018) reprocessed higher burn up uranium oxide fuels (Phillips and Milliken, 2000; Benedicic, 2017).

Nuclear fuel reprocessing by the PUREX process

Nuclear fuel reprocessing is generally used to describe the separation and purification of reusable uranium and plutonium products from irradiated nuclear fuel. The recovered U and Pu can then be converted in to new uranium oxide (UO_x) or mixed oxide (MO_x) fuels for recycle to reactors (Poinssot et al., 2012; Behar, 2014). The highly active (HA) fission product wastes are evaporated and then vitrified ready for disposal. By far the most successful reprocessing technology to date has been the PUREX process, which uses SX between aqueous nitric acid solutions and organic solutions of tri-*n*-butyl phosphate (TBP) diluted in a paraffinic diluent, such as Exxsol D-80 or hydrogenated tetrapropylene (TPH) (Denniss and Jeapes, 1996; Lecomte, 2008; Herbst et al., 2011; Netter, 2012).

A brief history of reprocessing

During the Manhattan Project and afterwards, large-scale plutonium processing used a bismuth phosphate precipitation method; this was then superseded by solvent extraction processes that could be run continuously, recover uranium and plutonium and

generated less wastes. The REDOX process, using methyl isobutyl ketone $[(CH_3)_2CHCH_2C(O)CH_3]$ or hexone as the solvent, was used at the Hanford site (United States) and the BUTEX process, based on dibutyl carbitol $(CH_3(CH_2)_3O(CH_2)_2)_2O$, was used in the United Kingdom at Windscale. However, the PUREX process was quickly shown to possess a number of process chemistry and chemical engineering advantages over these other processes, including being more stable, less flammable, salt-free extraction with better separations (Choppin, 2002). The PUREX process was first deployed at Savannah River in 1954 and has remained the dominant technology for processing nuclear fuel since the 1950s/60s (Nash and Nilsson, 2015). As of 2020, large scale PUREX reprocessing plants (~ 800 t/a) were in operation in the United Kingdom (Sellafield), France (La Hague), and Japan (commissioning at Rokkasho) but a number of other countries have experience of PUREX reprocessing at various scales, e.g. United States, Germany, Russia, Belgium, India (Netter, 2012). China, India and Russia are at various stages of developing new reprocessing capacity (Guoan and Taihong, 2015; Natarajan, 2017; WNA, 2020).

Historically, the United Kingdom, used in this article as a case study, has operated four reprocessing plants, although all will be in decommissioning by the early 2020s, see Table 1 for details (Benedicic, 2017). The two commercial scale reprocessing plants operated were the Magnox reprocessing plant which reprocessed uranium metal fuel from the domestic Magnox reactors and Thorp (Thermal Oxide Reprocessing Plant) which reprocessed domestic (AGR: Advanced Gas cooled Reactor) and overseas oxide (LWR: Light Water Reactor) fuels. Characteristics of these two plants are compared in Table 2 (Phillips and Milliken, 2000).

Reprocessing plant layout

A PUREX reprocessing plant comprises a number of facilities or capabilities: (a) ponds to receive and store spent fuel; (b) the Head End plant to prepare the fuel for reprocessing (disassembly) and to convert the fuel to a solution in HNO_3 ready for (c) chemical separation using solvent extraction to produce purified aqueous nitrate products that can be (d) converted to solid oxide products ready for manufacturing into new fuel. A substantial supporting infrastructure is necessary to (e) provide reagents needed for the process and (f) treat solid wastes and liquid and gaseous effluents arising from reprocessing operations.

This article covers the chemistry of the dissolution and conditioning process that prepares the aqueous phase for SX and the SX process itself. PUREX process flowsheets are all broadly similar with a number of solvent extraction cycles to separate and purify U and Pu from all other elements (a single SX cycle covers the extraction of a solute into the organic phase from the aqueous phase and the return of the solute back to the aqueous phase in a stripping or backwashing stage). The radiotoxicity of the elements and isotopes within CSNF means that reprocessing must obtain both very high recoveries of the product elements (U and Pu) and very high purities of these products from other isotopes. In separations chemistry, commonly, these two ambitions of high yields versus product purity are in opposition and this makes the reprocessing of CSNFG quite challenging from a technical perspective. Hence, to achieve U and Pu products of the desired purity the SX process must provide the requisite decontamination from fission products in the spent fuel. Decontamination factors are used as a measure of the process performance and are simply the ratio of the species concentration in the feed to the concentration in the product (Rydberg et al., 2004a,b). Over the entire SX process typical decontamination factors in the order of 10^6 – 10^8 are achieved so that U and Pu products can be used in fuel fabrication or enrichment plants without the need for remote handling in hot cells (Netter, 2012). As can be seen in Section “Magnox and thorp reprocessing” (in the evolution from Magnox to Thorp reprocessing), process development has been in the direction of reducing the number of solvent extraction cycles, adopting an early separation of Pu from U, using salt free reagents to minimize waste arisings and intensifying the contacting equipment, e.g., pulsed columns rather than mixer-settlers.

Table 1 UK reprocessing plants.

Dates	Plant	Description/status
1951–72	Windscale	Reprocessing plant for metal fuel, early commercial reactor fuel and dissolution of prototype oxide fuel
1960–96	Dounreay	Reprocessing of a variety of fuels from the UK fast reactor development programs
1964	Magnox	2nd reprocessing plant at Sellafield, reprocessed commercial Magnox clad uranium metal fuel
1994–2018	Thorp	3rd reprocessing plant at Sellafield, reprocessed commercial thermal oxide fuels (LWR and AGR)

Table 2 Characteristics of the fuels reprocessed and processes implemented in the Magnox and Thorp reprocessing plants.

Magnox	Thorp
Al/Mg clad U metal fuel from Magnox reactors	Stainless steel or zircaloy clad oxide fuel from AGRs and LWRs
Natural enrichment	Enriched U-235
Low burnup and short cooled fuel	High burnup and long cooled fuel
Mixer-settlers and 20% TBP	Pulsed columns and 30% TBP on Pu streams
Four cycle SX—“late split” flowsheet	Three cycle SX—“early split” flowsheet
Continuous dissolver	Batch dissolver
Salt containing flowsheet (ferrous, sulfate, Na ions)	Salt free flowsheet [U(IV) reductant, nitrogen oxide (NOX) gases]
Linked series of plants	Integrated plant

PUREX process chemistry

Dissolution process

Basic concepts

The “head-end” of an aqueous CSNF reprocessing plant converts the fuel into a form that is suitable for the solvent extraction purification process. Firstly, the disassembled CSNF must be transported from the fuel storage pool to a highly active cell where heavy engineering equipment is used to prepare the CSNF for chemical processing. Typically, this is done by mechanically shearing (cutting) the fuel rods into small pieces that can be fed to a dissolver for leaching the fuel out of the chopped pieces into hot nitric acid. The leached zircaloy hulls (cladding) are immobilized into a wasteform for disposal.

After the mechanical processes, chemical processing of CSNF in the head end involves fuel dissolution and liquor conditioning to prepare the feed for the separation process, whilst chemical and radioactive off-gases must also be treated to an appropriate degree. Dissolvers can be operated in either continuous or batch modes and whilst the basic chemistry is the same there are some subtle differences. As well as acid fumes, during dissolution the dissolvers are operated to allow efficient removal of $^{14}\text{CO}_2$, ^{129}I and ^{85}Kr ; a fraction of the tritium is also evolved. Dissolvers have air added to condensers to promote increased re-conversion of nitrogen oxides (NOx) generated from the dissolution to nitric acid thereby decreasing the amount of nitric acid used and the amount of nitrogen oxide fed to the dissolver off-gas (DOG) treatment plant. This technology is termed “fumeless” dissolution when operated at high efficiencies. Dissolvers use nitric acid recombination columns and caustic scrubbers to clean the gaseous streams, which are passed through high efficiency particulate (HEPA) filters before discharge via a stack. The caustic scrubbers efficiently remove ^{14}C which can be precipitated with barium carbonate (Maher, 2015).

There are several steps that are usually carried out after dissolution and before feeding to a solvent extraction process, these include:

- Iodine removal.
- Conversion of plutonium to the tetravalent state.
- Feed clarification.

Iodine removal is usually carried out during the dissolver cycle. An air sparge can be used to improve the efficiency. During irradiation of oxide fuel some of the fission product metals are not soluble in the fuel oxide structure and migrate to the fuel grain boundaries. These inclusions do not dissolve completely during a standard dissolution cycle and the residues are termed insoluble fission products (IFPs). The IFPs comprise of alloys of ruthenium, rhodium, palladium, molybdenum and technetium and may contain other metals including plutonium. A feed clarification step must remove solids that could interfere downstream with the SX process or block SX equipment—centrifugation or filtration are typical technologies.

Uranium oxide dissolution and the adjustment of plutonium oxidation states (conditioning) are specifically discussed in the next section.

Dissolution chemistry

The rate of dissolution of uranium oxide fuels is dependent on several factors including: nitric acid concentration, temperature, surface area, nitrous acid, volume, sparging and stirring. In plants where fuel rods are sheared and leached, dissolution efficiency will be affected by the size and shape of the hulls which can cause gas-locking. Overall, dissolution is thought to proceed according to Eqs. (1) and (3) where the key role of nitrous acid is evident (where $0 < x < 1$ in Eq. (3)) (Sakurai et al., 1988).

After dissolution and iodine removal, plutonium is usually present in the solution as a mixture of tetravalent and hexavalent oxidation states, Pu(IV) and Pu(VI). The tetravalent state is optimal for current TBP-based solvent extraction processes. Nitrogen dioxide (NOx gas) can be used to condition the plutonium to the tetravalent state via formation of nitrous acid and Eq. (4).

Solvent extraction (SX) process

Basic concepts

It is the choice of solvent extraction for actinide separation that drives many of the upstream and downstream processes; SX thus lies at the heart of nuclear fuel reprocessing. There are various advantages to SX including:

- Safe, low risk, mature technology.
- Easy to scale up and industrialize.
- High selectivities and high product purities achievable.

- Low temperature, low pressure processes.
- Can recycle and re-use solvent and aqueous phases.
- High heavy metal loading capacity.

Disadvantages include:

- Solvent degradation.
- Entrainment.
- Generation of secondary wastes (organic solvent and aqueous effluents).

An important concept is that industrial SX processes are run counter-current. That is, the aqueous and organic phases flow in opposite directions through a series of contactors, which are usually unit stages with both mixing and settling zones. Across this series of contactors, the feed is progressively depleted of the extractable solute until it exits the last contactor as a lean raffinate. The extracting phase, flowing in the opposite direction, exits the first contactor as a loaded product (Rydberg et al., 2004a,b). Fig. 1 illustrates this concept.

In applying SX to reprocessing of CSNF there are a range of additional problems to overcome compared to its use in more conventional process industries such as hydrometallurgy. These include radiation and radioactivity requiring remote operations, solvent radiolysis, criticality safety and radioactive waste management. The chemistry of the actinide elements and fission products in nitric acid also need to be considered, together with the choice of technology for solvent extraction. There are three types of contacting equipment typically considered for modern reprocessing plants: mixer-settlers, pulsed columns and centrifugal contactors. The principles of how these technologies operate are outside the scope of this paper and interested readers are referred to the references of Arm and Phillips (Arm and Phillips, 2011) and Hanson (2015) who describe in detail the engineering of solvent extraction in the PUREX process. It is sufficient here to note that these “contactors” must intimately mix the two phases (by generating a dispersed phase of very small droplets in a continuous phase) which enables transfer of chemical species to occur across the interface between the dispersed and continuous phases. The contactor must then separate out the phases (by gravity or centrifugal force) so they can be transported to the next stage of the process. Thus, from the chemical viewpoint, one important aspect to consider is whether the kinetics (rates of chemical reaction and/or rates of mass transfer between aqueous and organic phases) are compatible with the residence times in the solvent extraction contactor, which decrease in the order: mixer-settlers > pulsed columns > centrifugal contactors.

U and Pu extraction and separation process chemistry

In the PUREX process the purification of U and Pu from fission products is achieved by extraction of hexavalent and tetravalent metal nitrate complexes into 20–30% TBP (Eqs. (5) and (6)). The uranyl TBP complex is illustrated in Fig. 2 where it is seen that bidentate nitrate ions charge balance the UO_2^{2+} ion enabling two TBP molecules to complex the neutral nitrate species via the oxygen atoms of the P=O group (Lecomte, 2008). This species is then easily solvated in the non-polar organic diluent; that is, it is transferred across an aqueous/solvent interface from the bulk aqueous to bulk organic phase. Fig. 3 illustrates the classical 4-stage mechanism for this process (Rydberg et al., 2004a,b). In SX the amount of solute (e.g., uranium) extracted is usefully described by the distribution ratio (D), i.e., the ratio of a solute in the organic phase to that in the aqueous phase at equilibrium ($O/A = 1$), which itself is related to the equilibrium constant as shown in Scheme 1. In this example, it is apparent that distribution ratios for U(VI) are dependent on the nitrate concentration and uncomplexed or “free” TBP concentration (Rydberg et al., 2004a,b). In practice, this leads to a variation in $D_{\text{U(VI)}}$ with nitric acid as illustrated in Fig. 4.

U and Pu are then separated from each other by reductive stripping of Pu, whereby the similarly extractable tetravalent Pu is reduced to inextractable trivalent Pu and stripped to an aqueous phase, leaving U(VI) in the organic phase (Denniss and Jeapes, 1996). The distribution ratios for Pu(IV) and Pu(III) ions are compared in Fig. 2. Typically, a reductant such as uranous nitrate, $\text{U}(\text{NO}_3)_4$, is used to reduce Pu(IV) (Eq. 7) although ferrous ions, hydroxylamine (NH_2OH) and other reducing agents have been either used or proposed for this purpose, as have electrochemical and photochemical methods (Newton and Baker, 1967; Toth et al., 1977; Petrich et al., 1986; Miles, 1990). Of these other reducing agents, hydroxylamine is particularly relevant since

Fig. 2 Structure of $\text{UO}_2(\text{NO}_3)_2 \cdot 2\text{TBP}$ (hydrogen atoms not included).

Fig. 3 Proposed mechanism of U(VI) extraction by TBP (Rydberg et al., 2004a,b). Drawn by the author based on figure in Rydberg J, Cox M, Musikas C, Choppin GR (eds.) (2004) Solvent Extraction Principles and Practice. 2nd edn, Revised and Expanded, pp. 1–750, New York: Marcel Dekker, Inc.

Scheme 1 SX equilibria and distribution ratio using uranyl nitrate extraction into TBP.

it is salt-free and is suitable for use in both the uranium and plutonium purification cycles. Pu(IV) reduction by hydroxylamine (Eq. 8, excess hydroxylamine) is a quite complex reaction as it is strongly inhibited by acidity and the product Pu(III) ions (Eq. 9), where k is the rate constant and K_{Pu} is the dissociation constant for $\text{Pu}(\text{NO}_3)^+$ dissociation (Barney, 1976).

Fig. 4 U and Pu distribution ratios as a function of nitric acid concentration in the aqueous phase at equilibrium extraction of UO_2^{2+} , Pu^{4+} , Pu^{3+} ions and nitric acid into 30% TBP/diluent at 20 °C (modelled fits to experimental distribution ratios).

$$-\frac{d[\text{Pu}^{4+}]}{dt} = \frac{k[\text{Pu}^{4+}]^2[\text{NH}_3\text{OH}^+]^2}{[\text{Pu}^{3+}]^2[\text{H}^+]^4(K_{\text{Pu}} + [\text{NO}_3^-])^2} \quad (9)$$

A significant complication in the PUREX process is that Pu(III) is quite easily re-oxidized to Pu(IV) by nitric acid in a series of reactions that are autocatalyzed by nitrous acid (Eqs. 10 and 11) (Koltunov, 1974; Miles, 1990). To interrupt this process and stabilize Pu as Pu(III), an aqueous phase nitrous acid scavenger such as hydrazine is added to the U/Pu separation stages (Eqs. 12 and 13) (Perrott and Stedman, 1977).

However, although it is nominally considered to be “inextractable,” trace quantities of Pu(III) are extracted in to the solvent phase where, in the absence of a scavenger, re-oxidation to Pu(IV) does occur. In 2-phase mixed systems (i.e., HNO_3/TBP) this process is enhanced as the system tries to equilibrate, the ultimate effect being a requirement to add a substantial excess of reductant to maintain Pu in the trivalent state (Miles, 1990; Fox et al., 2006a,b). Once, U and Pu are separated, U can be backwashed into the aqueous phase by simply reducing the acidity to a low value, typically ~ 0.01 M HNO_3 . As U extraction is exothermic to improve the kinetics and shift the equilibrium of Eq. (6) to the left, backwashing is usually performed at an elevated temperature (Bagawde et al., 1978).

The solvent raffinates from the process, after U and Pu backwashing, contain degradation products due to radiolysis and hydrolysis of TBP. The main degradation products of concern are dibutyl phosphate (DBP) and monobutyl phosphate (MBP) since they can form strong complexes with actinide ions and some fission products (such as Zr), retaining them in the organic phase or forming cruds at the interface. This can have detrimental effects on process performance due to increasing losses of U and Pu to raffinate streams, deterioration of decontamination factors for some fission products, poor phase separation or risk of blockages. To avoid accumulation of degradation products in the solvent it is essential that there is a solvent wash process to remove these species and allow recycle and re-use of the solvent in the process. Typically, a standard solvent wash procedure with alkaline reagents is used to remove the acidic degradation products from the solvent (Lecomte, 2008).

Technetium

Technetium (^{99}Tc) is a fission product with a long half-life ($t_{1/2} = 2.11$ a) that increases in CSNF with increasing burn up. It is stable in acidic solutions as the anionic pertechnetate ion (TcO_4^-) and, as such, can replace nitrate ions in TBP complexes of U and Pu (Eqs. 14 and 15). It also strongly co-extracts with zirconium into TBP (Eq. 16) and, therefore, is a problem in PUREX flowsheets as it can be co-extracted with the (U, Pu)-containing organic phase (Herbst et al., 2011). Garraway and Wilson (Garraway and Wilson, 1985) reported a 1:1 complex for the Zr/Tc complex with TBP although separately Zr and Tc extract as higher complexes.

A further problem for the PUREX process is that technetium reacts with hydrazine which is used in the U/Pu separation stage to stabilize Pu(III) (Miles 1990, Denniss and Jeapes, 1996; Lecomte, 2008). Initially, there is a slow initiation phase in which Tc(VII) is reduced in stages to lower oxidation states leading to the build-up of Tc(IV). Tc(IV) can be re-oxidized either by remaining Tc(VII) ions or by nitrate and this leads to a catalytic cycle in which hydrazine is rapidly consumed. U(IV) enhances this process by initially reducing Tc(VII) quickly to Tc(IV). There is some debate about the exact mechanism but, based on references (Garraway and Wilson, 1984; Koltunov et al., 1986; Boukis, 1988), the general cycle of reactions with hydrazine is summarized in Fig. 5.

To date two main strategies have been employed to address the issues of technetium in PUREX reprocessing, viz the addition of a technetium rejection stage or the adjustment of conditions in the U/Pu separation to reduce the effects of this reaction to tolerable levels by adjusting the operating conditions in the pulsed columns where the U/Pu separation occurs. The basis of the former strategy, as used in the French La Hague UP3 reprocessing plant (Baron et al., 1993; Herbst et al., 2011), is illustrated in Fig. 6 which shows how Tc distribution ratios decrease as nitrate ion is increased.

Neptunium

Current practice in reprocessing plants is to treat the ‘minor actinide’ Np as a waste and to purify U and Pu products from Np, which is routed to high level wastes for vitrification (Fox et al., 2006b; Lecomte, 2008). However, this is not straightforward as Np exhibits a complex process chemistry. Np in solution can exist in oxidation states from III to VII; although in the PUREX process Np is usually present only as a mixture of Np(IV), Np(V) and Np(VI), as the ionic species Np^{4+} , NpO_2^+ and NpO_2^{2+} respectively (Drake, 1990; Yoshida et al., 2006). Acidity, nitrate ion concentration and temperature influence the equilibrium distribution of Np between these three oxidation states in nitric acid which readily inter-convert through reactions with $\text{HNO}_2/\text{HNO}_3$ and disproportionation/re-proportionation reactions (Drake, 1990). In the first extraction section of the PUREX process, the equilibrium between oxidation states (V) and (VI) (given in Eq. 17) is most important in determining the speciation and hence degree of extraction into the solvent phase. This equilibrium is dependent on the respective rates of the forward and reverse reactions which display quite complex kinetics due to the dual role of nitrous acid. From Eq. (17) it is apparent that HNO_2 reduces Np(VI) to Np(V) but it also acts as a catalyst for the oxidation of Np(V). Consequently, the kinetics and equilibria of this reaction have been studied quite extensively over the last 60 years (Siddall and Dukes, 1959; Gourisse and Gautier, 1969; Gourisse, 1971; Koltunov, 1974; Moulin, 1978; Tochiyama et al., 1995a, b; Gregson et al., 2012; Chen et al., 2016, 2017). For instance, Moulin (1978) proposed that the rate of oxidation is dependent on the ratio of nitrous acid to Np(V) and is given by Eq. (18) where k_x – k_e are individual rate constants.

Fig. 5 Technetium—hydrazine reaction cycles. Green arrows are initiation reactions, purple arrows are the catalytic cycle and yellow arrows are termination reactions.

Fig. 6 Tc distribution ratios as a function of nitric acid, also with zirconium and uranium present in solution (35 °C, extraction into 30% TBP/OK). Drawn by the author based on data in Garraway J and Wilson PD (1985) Coextraction of pertechnetate and zirconium by tri-n-butyl phosphate. *Journal of the Less-Common Metals* 106(1): 183–192.

$$-\frac{d[\text{Np(V)}]}{dt} = \frac{(k_\gamma[\text{H}^+] + k_\delta[\text{H}^+]^2 + k_\epsilon[\text{HNO}_2])[\text{NO}_3^-][\text{HNO}_2][\text{Np(V)}]}{k_\alpha[\text{HNO}_2] + k_\beta[\text{Np(V)}]} \quad (18)$$

The extraction of Np into TBP is also not straightforward. Np(IV) and Np(VI) are considered extractable, forming similar complexes to Pu(IV) and U(VI). Np(V) has a very low extractability into the PUREX solvent of 30% TBP/OK (tributyl phosphate diluted in odourless kerosene) and is generally considered inextractable (Drake, 1990).

As NOx conditioning of the dissolved CSNF solution in the Head End plant stabilizes Np as Np(V), partial oxidation to Np(VI) occurs by Eq. (17) in the initial (U, Pu) co-extraction stage in a reprocessing plant with the extent of oxidation depending on solution conditions and residence times in the contactor. This leads to Np being split between the Highly Active (HA) raffinate (Np(V) ions) and (U, Pu) containing TBP phase (Np(VI) ions) (Dinh et al., 2008; Taylor et al., 2013). In the U/Pu split, U^{4+} will reduce neptunium to Np^{4+} (Eqs. 19 and 20) which, depending on acidity and O/A ratio can be co-extracted with U (Newton and Baker, 1967). This necessitates a second solvent extraction cycle in which the U product is decontaminated from Np. This can be achieved by oxidizing Np^{4+} back to Np(V) and Np(VI) and then reducing any Np(VI) formed to inextractable Np(V) with a selective reducing agent. Hydroxylamine is commonly used for this purpose (Eq. (21)) as it is a rapid reductant for Np(VI) and does not reduce Np(V) to Np(IV) or reduce U(VI) (Koltunov and Tikhonov, 1977).

Third phase formation

So far, the basic PUREX process chemistry has been described through the extraction reactions for U and Pu, and their dependence on nitric acid concentration, and the redox chemistry of Pu, including the need for a nitrous acid scavenging agent to stabilize the Pu(III) state. The mechanism of extraction via reactions at the organic/aqueous interface has been discussed for uranyl nitrate as an example. The cases of two specific problematic elements were then considered with respect to their process chemistry: technetium and neptunium. However, there are many other facets of PUREX process chemistry (and chemical engineering) that must be considered when developing the flowsheet or supporting the safety case. One specific example is third phase formation. This is an effect in solvent extraction whereby the organic phase when heavily loaded with nitric acid and/or metal ions splits into two layers: a lighter diluent-rich and a heavier TBP-rich layer (Rao and Kolarik, 1996; Rydberg et al., 2004a,b). This has serious implications for process efficiency and process safety as it can cause phase inversion, leading to misrouting of U or Pu, and the third phase can become heavily loaded with Pu, thus presenting a criticality hazard (Plaue et al., 2006a,b,c). The PUREX process must be operated in regions well below the limits for third phase formation.

Fig. 7 Example third phase data for actinide extraction into TBP: (A) variation of Limiting Organic Concentrations (LOC) with tetravalent and hexavalent actinide ions (extraction from 7 M HNO_3 into 30% TBP/dodecane) (Plaue et al., 2006a,b,c); (B) Effect of different diluents on LOC (TPH, Shellsol-SST and dodecane) (Plaue et al., 2006a,b,c). (A): drawn by D Whittaker of NNL for the author based on data in Plaue J, Gelis A and Czerwinski K (2006b) Actinide third phase formation in 1.1 M TBP/nitric acid/alkane diluent systems. *Separation Science and Technology* 41(10): 2065–2074.; (B) Drawn by D Whittaker of NNL for the author based on data in Plaue J, Gelis A and Czerwinski K (2006c) Plutonium third phase formation in the 30% TBP/Nitric Acid/Hydrogenated polypropylene tetramer system. *Solvent Extraction and Ion Exchange* 24(3): 271–282.

In determining third phase boundaries, it is usual to find the point at which the third phase forms, this is defined either as the limiting organic concentration (LOC) or critical aqueous concentration (CAC). Example LOC data for the series of hexavalent and tetravalent actinide ions, U to Pu, are given in Fig. 7A (note that U(VI) does not form a third phase under these conditions) (Plaue et al., 2006a,b,c). Generally, in the PUREX process it is the tetravalent actinide ions that present the greater challenge with respect to third phase formation, Pu^{4+} being of primary concern. It is seen here and elsewhere that different metal ions behave quite differently with respect to third phase formation and that the LOC changes over the nitric acid range. For instance, plutonyl (VI) ions, PuO_2^{2+} are much more susceptible to third phase than the analogous UO_2^{2+} ions (Plaue et al., 2006a,b,c). To generalize, increasing temperature, extractant concentration, and ionic strength increase LOC, as does decreasing the carbon chain length of the diluent. In fact, third phase formation is very dependent on the nature of the diluent as can be seen in Fig. 7B (Plaue et al., 2006a,b,c). It is clearly established that branched alkanes reduce the likelihood of third phase and modifiers, such as alcohols or aromatics, that increase the polarity of the diluent also inhibit third phase formation. Industrially, diluents comprising mixtures of branched alkanes with densities similar to *n*-dodecane are used in reprocessing; for example, TPH or Exxsol D-80. Mechanistically, third phase

has been described in two basic ways: either by the formation of specific solvates (adducts) that form on high loading in the organic phase (e.g., Eq. 22 (Kumar and Koganti, 2003)) or by the association of small reverse micelles which form in the organic phase. These reverse micelles contain several TBP molecules around a polar core of metal ion, nitric acid and water molecules. As the micelles swell with increased organic phase loading, they interact through van der Waals forces until, at a critical value of interaction energy, phase separation takes place (Chiarizia et al., 2003a,b; Nave et al., 2004; Plaue et al., 2006a,b,c; Antonio et al., 2018). The Baxter sticky spheres model has been widely used to describe the particle interactions. The speciation in the organic phase that leads to third phase formation is a very topical area of fundamental study in the field of solvent extraction of actinides. Despite nearly 70 years of PUREX research, there remain gaps between results from these experimental speciation studies, solvent extraction calculations (Kumar and Koganti, 2003; McLachlan et al., 2016) and molecular modelling (Ivanov et al., 2017; Chandrasekar et al., 2019) that such basic research is now filling.

Magnox and Thorp reprocessing

Magnox reprocessing

The Magnox reprocessing plant was commissioned in 1964 to reprocess spent uranium metal fuel from the UK's Magnox reactors. Fuel rods were mechanically declad and uranium rods fed to a continuous dissolver prior to PUREX reprocessing. The solvent extraction flowsheet was based on a late split; that is, there was an initial co-decontamination cycle of U and Pu from fission products before U and Pu were separated from each other. U and Pu separation used ferrous ions (Eq. 23) to reduce Pu(IV) to Pu(III) and sulfamate ($NH_2SO_3^-$) ions to scavenge nitrous acid (Eq. 24) to prevent re-oxidation of Pu(III). Following U and Pu separation, separate purification cycles were employed to reach high DFs on the U and Pu products (i.e., four SX cycles in total). As Magnox reprocessed short cooled low burn up fuels, decontamination from ruthenium, zirconium and niobium fission products was one of the key issues. Due to low Pu concentrations, solvent extraction used 20% TBP and mixer-settlers. Solvent wash for high active, plutonium active and low active solvents from separate SX cycles were used to enable recycle of solvent within the process. U and Pu products were converted to solid oxides by thermal denitration and oxalate precipitation processes respectively. The use of salt-containing reagents in the process, such as ferrous sulfamate, increased the complexity of downstream waste treatment as well as waste volumes generated.

Thorp reprocessing

The United Kingdom Thorp reprocessing plant exemplified the modern approach to conventional PUREX reprocessing. Following disassembly, fuel rods were sheared into small pieces and leached in a batch dissolver. Following dissolution of the CSNF in nitric acid, U and Pu are purified by SX. As illustrated in Fig. 8 (Baron et al., 2019), Thorp used three solvent extraction cycles with an early split flowsheet, i.e., U and Pu are extracted away from the fission products and then separated from each other in the first or HA cycle of solvent extraction. This was achieved despite Thorp processing higher burn-up, enriched oxide fuel from AGRs and LWRs. Unlike Magnox, Thorp used only salt free reagents in the core separation process. U and Pu were separated from each other by a mixture of U(IV) and hydrazine (N_2H_4), as indicated by Eq. (7) and Eq. (12) above. Due to the co-extraction with U, Pu and Zr (Eqs. 14 and 16) and the reactions with U(IV) and hydrazine (Fig. 5), Tc mainly followed the Pu product. This contrasts with Np which was mainly split between the HA raffinate and the U product due to the equilibrium between inextractable Np(V) and extractable Np(VI) (Eq. 17). Following conditioning of the backwashed aqueous products, there were then two further SX cycles to purify the uranium product stream and the plutonium product stream. Uranium purification (UP) provided an additional decontamination from neptunium and residual plutonium whilst plutonium purification (PP) removed technetium from the product. Both UP and PP increased the overall decontamination factors from fission products such as ^{106}Ru , $^{134,137}Cs$ and ^{144}Ce (Phillips, 1996; Burrows et al., 2006). UP and PP cycles used hydroxylamine nitrate as the reducing agent (see Eq. 8 and Eq. 21).

For improved criticality safety and to reduce solvent degradation, pulsed columns were used for the Pu bearing streams whereas mixer-settlers were used for U-streams post U/Pu separation. As in Magnox reprocessing, solvent wash cycles, based on a carbonate washing process, enabled used solvent to be recycled back into the process. Following SX, U and Pu products were converted into solid oxides suitable for interim storage before manufacture into new fuels. The conversion processes used were a thermal denitration (TDN) process for Uranium Finishing and an oxalate precipitation and calcination process for Plutonium Finishing. The Thorp plant was integrated with the other supporting operations such as CSNF receipt and storage, plutonium product storage, waste management plants and MOx fuel fabrication (Phillips and Milliken, 2000). The French La Hague reprocessing plant is similar in design although technetium (a problematic fission product) is back-washed out of the (U, Pu) solvent product prior to the U/Pu separation stage to avoid the complications described in "Technetium" section (Lecomte, 2008).

Fig. 8 Thorp solvent extraction flowsheet for commercial scale oxide fuel reprocessing (Sellafield, United Kingdom). Reproduced from ref. Baron P, Cornet SM, Collins ED et al (2019) A review of separation processes proposed for advanced fuel cycles based on technology readiness level assessments. *Progress in Nuclear Energy* 117: 103091.

Future perspectives

Despite the proven utility and established operational experience of the PUREX process, which is underpinned by a large body of knowledge and data, there is still room for improvements in its application for future reprocessing in closed nuclear fuel cycles. Indeed, the development of advanced or modified PUREX processes must be a major component of any program considering aqueous based technology for fuel processing. How radical any changes to the PUREX process can be depends on timescales to deployment. For near term deployment PUREX flowsheets based on conventional designs (such as those used at Thorp or La Hague plants) will have to be considered, possibly with evolutionary modifications such as those proposed in the French COEX™ process which produces a mixed U-Pu product to improve the anti-proliferation characteristics of the plutonium product (Senentz et al., 2009; Herbst et al., 2011; Poinssot et al., 2012).

Longer term R&D programs are generally more ambitious aiming for significant adaptations of the PUREX process that substantially reduce capital costs and address other perceived shortcomings of the conventional PUREX process for applications in future nuclear fuel cycles (Baron, 2010; Cashmore and Koppelman, 2015; Glatz et al., 2015; Guoan and Taihong, 2015; Minato, 2015; Todd, 2015; Baron et al., 2019). Hence, the actinides U, Np and Pu need to be fully controlled, ideally within a single PUREX solvent extraction cycle that is flexible to a wide range of feeds—higher burnup fuels and MOx fuels, for instance. A future process must probably meet similar product specifications on the U stream as currently but display increased barriers to proliferation on Pu streams, such as dilution with U and/or increased radiation fields (lower DFs). There are advantages if this can be achieved within short residence time annular centrifugal contactors, using kinetically fast “CHON” reagents only, producing minimized volumes of easily treated product and effluent streams. (The “CHON Principle” indicates that the reagent contains carbon, hydrogen, oxygen and nitrogen only and so can be completely decomposed without adding to the waste volumes). Greater use of modern technologies for on-line process monitoring will be needed to enable process control and accountability in real time. Waste arisings must be minimized at source and hazardous process reagents such as hydrazine replaced, if possible, with an increased robustness towards process upsets.

Hence, it is seen that recent progress internationally includes, inter alia, the development of single cycle PUREX flowsheets (Birkett et al., 2005; Lumetta et al., 2019); replacement of U(IV)/hydrazine for reductive stripping of Pu with a single complexing agent (Birkett et al., 2005; Carrott et al., 2007); development of real time process monitoring and control through on-line spectroscopic methods (Asmussen et al., 2019; Lumetta et al., 2019); use of TBP analogues that reduce risks of third phase formation (Sreenivasulu et al., 2016; Chandrasekar et al., 2017); improved Np control (Dinh et al., 2008; Taylor et al., 2013), etc. Elsewhere, the replacement of TBP itself by a CHON extractant, e.g., an amide (Manchanda and Pathak, 2004; McCann et al., 2018) or use of crystallization for the initial co-decontamination step (Washiya et al., 2009; Takeuchi et al., 2016) offer even more fundamental changes to the separation process. Lastly, much work has been undertaken in recent decades to extract the trivalent minor actinides (americium and/or curium) from the PUREX HA raffinate to reduce the radiotoxicity and heat loading of the high level waste that is ultimately sent to the geological repository (Baetslé et al., 2004; Grenèche et al., 2008; Baron, 2010; Modolo et al., 2015; Moyer et al., 2015; Collins et al., 2018). This requires the development of completely new separation processes (trivalent actinides are inextractable into TBP). It is

indicative of the success of the PUREX process that most of these are based on solvent extraction from nitric acid, e.g., see (Modolo et al., 2015; Moyer et al., 2015; Sharrad and Whittaker, 2015; Collins et al., 2018).

Conclusions

The PUREX process has proven to be a very successful process for the recovery of U and Pu from CSNF and has been operated at commercial scales in a number of countries. The process is based on the solvent extraction of U and Pu from an aqueous nitric acid phase into an organic phase of tri-butyl phosphate in a paraffinic diluent. There is a very good chemical and engineering basis to the PUREX process generated from over 70 years of research but options still exist to update and improve the process for “advanced” reprocessing applications in future closed nuclear fuel cycles. Specifically, the challenges in controlling neptunium and technetium are highlighted due to their complex process chemistry.

Introduction

Pyrochemical processes have been studied for more than 70 years for recovering and purifying actinides, and in particular plutonium, and later, for recovering all actinides from spent nuclear fuel. Although they are based on a quite simple chemical concept, their implementation and their monitoring reveals to be quite complex as this chapter will demonstrate.

The actinide chemistry in molten salts was first studied in the 1950s for developing the Aircraft Reactor Experiment (ARE) (Bettis et al., 1957), and then in the 1960s for the Molten Salt Reactor Experiment (MSRE) (Robertson, 1965). In both experiments, the molten salt was a molten fluoride salt containing uranium, plutonium and/or thorium. The next step was the development of the Molten Salt Breeder Reactor (Robertson, 1971), with online pyrochemical processing. However, these developments were stopped by 1975 to focus on the development of light water reactors with solid fuels. In the 1980s, there was a renewal interest of pyrochemical processes for the processing of fast reactor metallic fuel in the frame of the Integral Fast Reactor concept (IFR) (Ackerman, 1991). In this case, the molten salt was a chloride salt (LiCl-KCl eutectic). The process was implemented up to the pilot scale for the recovery of uranium, and only to the lab scale for the recovery of the transuranic elements. Again, the developments were stopped in the mid-1990s.

There was a renewal of such studies at the end of the 1990s, with Japan, South Korea, Russia and France, with different perspectives and applications on metallic or oxide fuel, but also a renewal of the studies on molten salt reactor concepts, which remain today the main field for molten salt chemistry developments.

After a description of the chemical basis in molten salt, the main process options will be presented and illustrated by the key demonstration projects.

Finally, the challenges still to be addressed will conclude this article.

Chemical basis for pyroprocesses

The molten salts

Molten salts are ionic liquids composed of anions and cations. The most common anions are the halides (chloride, fluoride), but could be nitrate or carbonate. The cations are alkaline or alkaline earth elements. The most studied molten salt is the LiCl-KCl eutectic (59.2/40.8) with a melting point of 353 °C.

They are very good heat conductors (KCl at 800 °C is 22 times more conductor than water at 20 °C) and excellent ionic conductors. Depending on the choice of the anions and cations, the structure of the salt can range from a fully dissociated mixture of anions and cations to an organized complex liquid with ion pairs or molecules. A mixture of two different salts can present specific properties and have a strong non-ideal behavior, opening the field for more process applications.

Fig. 1 Phase diagram of LiCl-KCl, NaCl-KCl and NaCl-AlCl₃ salt. Data from FTSalt—FACT Salt Database, http://www.crct.polymtl.ca/fact/documentation/FTsalt/FTsalt_Figs.htm

Generally, alkaline halide mixtures exhibit low deviation to ideality, whereas when one of the cation is not an alkaline (or alkaline earth), such as aluminum, the mixture can present strong deviation. In such a case, the mixture will behave like a Lewis acid, the acidity depending on the ratio of the two salts (**Fig. 1**).

The solubility of actinides and lanthanides can be very high in some salt, when a binary or ternary eutectic composition exists (up to 40 mol%) (**Figs. 2 and 3**).

Thermodynamics

The chemistry in molten salt is driven by the thermodynamics.

For a **reaction (i)**, the Gibbs energy (or free enthalpy of formation) ΔG is defined by Eq. (1), where A,B,C,D are four chemical species, n_i the number of mole of I, ΔG° the free energy of formation of the pure compounds, a_i the activity of I in its phase. The activity is linked to the molar fraction X_i by Eq. (2), where γ_i is the activity coefficient of i in the studied media (when a species is alone in its phase, the activity coefficient is 1). R is the gas constant ($8314 \text{ J mol}^{-1} \text{ K}^{-1}$) and T is the temperature in Kelvin.

$$n_A A + n_B B = n_C C + n_D D \quad (i)$$

$$\Delta G = \Delta G^\circ + RT \ln \frac{a_C^{n_C} a_D^{n_D}}{a_A^{n_A} a_B^{n_B}} \quad (1)$$

$$a_i = \gamma_i X_i \quad (2)$$

Fig. 2 Binary phase diagrams of the NaCl-CeCl₃ (—) and NaCl-PuCl₃ (—) systems. From Sooby AS et al. (2015) Measurements of the liquidus surface and solidus transitions of the NaCl-UCl₃ and NaCl-UCl₃-CeCl₃ phase diagrams. *Journal of Nuclear Materials* **466**: 280–285.

Fig. 3 Isothermal projection of the LiCl-KCl-UCl₃ system at 773 K. From Hames A et al. (2018) Phase equilibria studies of the LiCl-KCl-UCl₃ System. *Nuclear Technology* **203**: 1–10. doi: 10.1080/00295450.2018.1448673.

The redox potential E and the Gibbs energy ΔG are linked by Eq. (3), where n is the number of exchanges electrons and F the Faraday number ($F = 96.487 \text{ } ^\circ\text{C}$).

$$\Delta G = -nFE \text{ or } E = -\Delta G/nF \quad (3)$$

Fig. 4 Free energy of formation of pure compounds, built from HSC and f-MPD databases (own work).

All the chemistry, or electrochemistry, in molten salts is driven by these few equations. The main difficulty is the determination of the activity coefficients, which depend on the media and can only be experimentally determined. Different databases list the free energy of formation of pure compounds (such as Outokumpu HSC), in particular actinide and lanthanide halides (Fig. 4).

These activity coefficients must be determined for the species in molten salts, but also for the reduced species recovered in a metallic solvent or deposited on a cathode made of a metal able to dissolve (alloy formation) or form polymetallic compounds with these species (Fig. 5).

A molten salt has a stability chemical domain (also called electrochemical window) defined by the reduction of the less stable cation on one side and by the oxidation of the anion on the other side. Within this domain, it is possible to perform redox chemistry or electrochemistry on, or between, any dissolved species having a Gibbs energy (or free enthalpy of formation), ΔG , or a redox potential, E , within this window. In the case of LiCl-KCl, the less stable cation is Li^+ (Fig. 6).

Therefore, in molten chloride salt such as the LiCl-KCl eutectic, this can be summarized by Fig. 7.

Similar determination was made for different metals on or in which the species can be reduced (Fig. 8). When the deposited metal can react with the metallic substrate (Cd, Bi, Al), the reduction is easier (depolarization phenomenon) than with an inert substrate (such as tungsten) but the gap between the reduction potential of two species is lower, meaning that the selectivity will be lower too. The highest selectivity between actinides and lanthanides is with tungsten, then aluminum. With Cd and Bi, the selectivity is poor.

It is also important to monitor and control the oxide content in the salts, since it can influence the speciation of the actinides and lanthanides. It allows a specific chemistry based on the selective formation of oxide species. Such an approach was used by the RIAR in Russia to develop the Dimitrovgrad Dry Process. Pourbaix diagrams (or predominance diagrams) can help to determine the potential and the oxide concentration at which either a selective precipitation or a redox reaction is possible (Figs. 9 and 10).

Based on this information, pyrochemical separation processes can theoretically be developed and tentatively industrially deployed.

From the chemical reactions to a potential separation industrial scheme

Based on the previous statements, three kinds of separation processes can be developed. Two are directly based on the redox chemistry by mastering the potential either by electrochemistry or by a chemical reagent. The third one is based on oxide or oxychloride precipitation by controlling the concentration of oxide ions in the salts.

Spent nuclear fuel dissolution is molten salt

For some separation processes, the spent fuel needs to be first dissolved in the molten salt. This is the case the liquid-liquid extraction process, for a precipitation process or for an electroreduction (or electrowinning) process such as the DIMITROVGRAD Dry Process. This dissolution can be quite challenging.

Oxide fuels can be dissolved by a carbochlorination process following [reaction \(ii\)](#) (see for example [Dobbins and Burnet, 1988](#)).

Excess of chlorine gas must be used to avoid the formation of soluble oxychloride species.

Chemical processes

If a metal for which the ΔG of formation of its halide is between the ones of lanthanides and actinides is contacted with the salt, it will selectively reduce the actinides to the metallic form, whereas the lanthanides will remain in the salt under cationic form Conocar et al. (2005a). For instance, lithium metal, which is more reductive than both lanthanides and actinides, will reduce both actinides and actinides to the metallic form.

R is the reductive metal, dissolved in the metallic solvent (the reductive metal can be the solvent)

$$K = \frac{a_M a_{RX_z}^{y/z}}{a_{MX_y} a_R^{y/z}} \quad (4)$$

$$\log D_M = \frac{Y}{Z} \log D_R + \log K + \log \left(\frac{\gamma_{MX_Y} \gamma_R^{Y/Z}}{\gamma_M \gamma_{RX_Z}^{Y/Z}} \right) \quad (5)$$

$$\left\{ D_M = \frac{X_M}{X_{MX_Y}} \right. \quad (6)$$

In chemical reduction processes, the challenge is the identification of the reductive metal that will selectively reduce the actinides and the identification of the metallic solvent. However, as shown in Eqs. (4) and (5), the activity coefficients of species both in the salt and in the metal are key parameters and the selection of the reductive metal cannot be based on the free enthalpy of formation. If the ratios of the activity coefficients of two species are almost always close to 1 in molten salts, they can vary on a broader range of several orders of magnitude in the metallic phase.

When considering the equilibrium between two species (for instance actinides vs. lanthanides) shown in reaction (iv), the selectivity is expressed by the separation factor SF_{ij} . SF_{ij} is defined as the ratio of the distribution coefficients D_{Mi} and D_{Mj} (Eq. 8) (Conocar et al., 2005b).

With

$$K_{ij} = \frac{a_{MjX_3} a_{Mi}}{a_{MiX_3} a_{Mj}} \quad (7)$$

$$SF_{ij} = D_{Mi}/D_{Mj} \quad (8)$$

By combining Eq. (5), Eq. (7) and Eq. (8), it gives Eq. (9)

$$SF_{ij} = K_{ij} \frac{\gamma_{MiX_3} \gamma_{Mj}}{\gamma_{MjX_3} \gamma_{Mi}} \quad (9)$$

Where K_{ij} depends only on the Gibbs energy of formation of M_iX_3 and M_jX_3 , $\frac{\gamma_{MiX_3}}{\gamma_{MjX_3}}$ represents the solvation differential in the salt and $\frac{\gamma_{Mj}}{\gamma_{Mi}}$ represents the solvation differential in the liquid metal.

For M_i being an actinide and M_j a lanthanide, the solvation differential in the salt is close to 1.

The situation is very different for the solvation differential in the liquid metal. This parameter has to be minimized to increase the separation factor.

An illustration of the solvation differential is given for different metals as a function of the temperature (M_i = plutonium and M_j = Cerium) on Figs. 11 and 12. It shows that aluminum is the best metallic solvent.

Indeed, the most efficient process was proposed in molten fluoride salt $LiF-AlF_3$, with the aluminum as both the liquid metal phase and the reductive metal. The use of AlF_3 bring another parameter into the system: the fluoroacidity concept. For instance, in the LiF/AlF_3 mixture, LiF is totally dissociated as Li^+ and F^- whereas AlF_3 is a F^- acceptor, leading to the formation of AlF_3^{x-} depending on its molar fraction. This fluoroacidity also affects the activity coefficients in the salt (Fig. 13).

It has to be noticed that the spent fuel has to be first dissolved in the salt before the extraction process.

Electrochemical processes

The same results can be obtained by electrochemistry, by applying a cathodic potential between the redox potentials of lanthanides and actinides. The reduced metals are deposited on the cathodic material (Laidler et al., 1997). This second option is more flexible since any potential can be applied precisely, but it will require more energy than the chemical method.

The selectivity will depend on the gap between the reduction potential of the two species to be separated. It can be estimated by using the Nernst equations (Eq. 10).

$$E = E^\circ + 2,3RT/nF \log(ox/red) \quad (10)$$

Let's consider the selective recovery of an actinide (An) from neodymium (Nd). For each element, Eq. (10) can be written as:

$$E_{Nd(III)/Nd(0)i=0} = E_{Nd(III)/Nd(0)}^0 + \frac{2,3 \times RT}{3F} \log[Nd(III)] \quad (11)$$

$$E_{An(III)/An(0)i=0} = E_{An(III)/An(0)}^0 + \frac{2,3 \times RT}{3F} \log[An(III)] \quad (12)$$

Then, the gap between the two reduction potential is given by Eq. (13)

$$\Delta\Delta E = E_{Nd(III)/Nd(0)}^0 - E_{An(III)/An(0)}^0 = -\frac{2,3 \times RT}{3F} \log \frac{[Nd(III)]}{[An(III)]} \quad (13)$$

Fig. 11 Variation of $\log \gamma_U - \log \gamma_{Ce}$ and $\log \gamma_{Pu} - \log \gamma_{Ce}$ versus temperature for various metals. From Conocar O et al. (2005b) Extraction behavior of actinides and lanthanides in a molten fluoride/liquid aluminum system. *Journal of Nuclear Materials* **344** (1–3): 136–141.

Fig. 12 Pu, Am, Ce and Sm partitioning in the $\text{MIF-AlF}_3/\text{Al-Cu}$ system: effect of the salt composition. From Conocar O et al. (2005b) Extraction behavior of actinides and lanthanides in a molten fluoride/liquid aluminum system. *Journal of Nuclear Materials* **344** (1–3): 136–141.

Where $\log[\text{Nd(III)}/\text{An(III)}]$ is the logarithm of the separation factor of the two elements.

If we want to achieve a separation factor between An and Nd of 10,000, then

$$\Delta\Delta E = E_{\text{Nd(III)}/\text{Nd(0)}}^0 - E_{\text{An(III)}/\text{An(0)}}^0 = -4 \frac{2.3 \times RT}{3F} \quad (14)$$

It gives a minimum gap of 190 mV at 450 °C and a gap of 285 mV at 800 °C.

According to Fig. 7, this is achievable for selectively recovering U and Pu, but much more challenging for americium.

However, when the composition of the salt is complex, the metallic cathodic deposit can reduce other cations which are in the salt and then be re-oxidized and re-dissolved in the salt. This is what happens when plutonium is reduced whereas there is still uranium chloride in the salt. An alternative is to use a reactive cathodic material, which will form an alloy or a solid solution with the reduced metal. The most studied reactive cathode material is the cadmium, but aluminum could be a good alternative since thermodynamics demonstrates that the selectivity is higher on aluminum.

Fig. 13 Electrorefiner conceptual diagram. Ackerman JP (1991) Chemical basis for pyrochemical reprocessing of nuclear fuel. *Industrial and Engineering Chemistry Research* **30**(1), 141, doi: 10.1021/ie00049a022.

Two types of process can be developed: the electrowinning, or electrodeposition, where the spent fuel is first dissolved in the molten salt, and the electrorefining where the treatment is directly applied to the spent fuel and allows a metal to metal direct processing.

An electrorefining process is more efficient than an electrowinning process because the concentration of the species to be reduced remain higher in the salt, allowing a higher selectivity. However, the electrorefining alone does not allow the quantitative recovery of all the actinides. It is particularly well suited for the recovery of the uranium.

This explains why electro-pyrochemical processes in molten chlorides are particularly well suited for the processing of metallic fuels. The actinides, which are the elements to recover from the spent fuel, are the first selectively reduced.

Selective precipitation

Actinides can be removed from a molten by oxidizing them into solid oxide or oxychloride species (Lambertin et al., 2002, 2003; Caravaca et al., 2008). Such a precipitation can be obtained by adding an oxidizing reagent such as calcium carbonate or sodium carbonate (McNeese et al., 1995), oxygen sparging (Cho et al., 2006) or by wet gas sarging (Vigier et al., 2013). However if the concept is simple and good performances seem to be achievable based on Pourbaix diagram analysis, the selectivity observed in experiments is poor (Lambertin, 2001).

Such a process can be used for oxide recovery from molten salt in order to fabricate fresh fuel (Vigier et al., 2013).

Current experimental feedback and key demonstration projects

Based on the chemical properties described above, two kind of salts can be used (chlorides and fluorides) and two types of methods (chemical or electrochemical).

The first and most studied combination is the electrorefining in molten chloride for the processing of metallic spent nuclear fuel. Two examples will be developed: the reference process developed in the frame of the IFR project and the process developed in Europe at the JRC Karlsruhe.

The second option is the Dimitrovgrad Dry Process for fast MOX fuel reprocessing.

The third option is the chemical liquid-liquid reductive extraction process between a molten fluoride salt and liquid aluminum developed at the CEA.

Electrorefining process

In the 1980s, the IFR project was based on a processing of fast reactor metallic fuel after short cooling time, in a facility near the reactor. Pyroprocesses are deemed compact and suitable for small units. The process was based on two steps: first the recovery

Fig. 14 Process scheme for spent fuel processing in molten salt by electrorefining. From Chang Y (2002) *Advanced Nuclear System for the 21st Century, Workshop on Nuclear Cycle System for the 21st Century, Karlsruhe, Germany, 6–8 May*.

of pure metallic uranium by direct electrorefining of the spent fuel, and second a recovery of the plutonium and the minor actinides by an electrolysis on liquid cadmium (Ackerman, 1991) (Fig. 13). An additional step at the head-end of the processed allowed the processing of LWR oxide fuel through an oxide reduction process prior the electrorefining (Fig. 14) (Chang, 2002).

The first step was extensively studied and developed up to the pilot scale at Idaho Falls National Laboratory. A dedicated electrorefiner was built (Ackerman, 1991) and upgraded up the fifth version, Mark V (Fig. 15). A few tons of EBR II blanket fuel were processed.

However, the recovery of plutonium and minor actinides on the liquid cadmium cathode was mainly developed up to the engineering-scale (a few kilograms) with many technical challenges in the handling of this liquid cathode and limited decontamination factors of the plutonium versus the lanthanides (Li et al., 2009, 2010; Vaden et al., 2008).

In the meantime, similar developments were carried out in Japan (Koyama, 1997; Iizuka et al., 1997; Kato et al., 2006). Decontamination factor of Pu (ratio of neodymium to plutonium concentrations, $[Nd]/[Pu]$, in the salt before extraction to that in the cadmium after extraction.) calculated from the reported experiments are about 25 for the best ones.

In South Korea, KAERI has also carried out technology developments for the scale-up of the pyroprocess proposed by INL. The PRIDE facility was designed to demonstrate engineering-scale pyroprocessing in an integrated manner (Fig. 16). The PRIDE facility included all the technological devices for testing the oxide reduction, the uranium electrorefining and the plutonium and minor actinide electrolysis on cadmium (Lee and Jang, 2017). However, KAERI can only work with uranium and the electrolysis was never tested with plutonium and minor actinides.

In these processes cadmium has been chosen for its high volatility which allows its distillation and therefore an easy recovery of the pure transuranics at the metallic state.

However, very few experiments were carried out on Pu-Am loaded cathodes.

The electrochemical reprocessing of oxide fuels has also been proposed, including a pretreatment in which the oxide fuel is reduced to the metallic state (Williamson and Willit, 2011) (Fig. 17).

Electrochemical European process using an aluminum cathode

Since the early 2000s, an electrorefining process allowing the recovery of both the uranium and the transuranics on a solid aluminum cathode has been studied at the JRC Karlsruhe (Serp et al., 2005). As reminded in the first part of this article, aluminum is the best reactive cathode material for the selective recovery of actinides.

However, such a process has only been demonstrated at the lab-scale and still requires engineering and upscaling developments. The redox potentials of U, Pu and Am on Al show that U could be recovered alone but the gap between Pu and Am potentials makes the recovery of pure plutonium very challenging.

This process has been tested on a METAPHIX fuel in the frame of the JRC/CRIEPI collaboration (Soucek et al., 2019).

- Efficient recovery of actinides from irradiated metallic fuel METAPHIX-2 was demonstrated by electrorefining process.
- High separation factors of actinides (An) over lanthanides (Ln) were achieved in electrolyte with high concentration of Ln.
- Grouped selectivity of the actinides recovery was proven for later and final stages of the electrorefining process.

Fig. 17 Conceptual flowsheet for the treatment of used LWR fuel. From Williamson MA and Willit JL (2011) Pyroprocessing flowsheets for recycling used nuclear fuel. *Nuclear Engineering and Technology* 43(4).

- Aluminum cathode was proven suitable for recovery of all actinides, while only uranium was deposited on the inert cathodes.
- Zirconium co-dissolution from the fuel had no effect on the process efficiency and on the structure of the deposits.

A weak point of such a process is the recovery of the actinides from the aluminum matrix. Two options have been studied: the selective chlorination of Al as AlCl_3 under controlled conditions to avoid the formation the volatile actinide chloride species (Cassayre et al., 2011; Soucek et al., 2014) or the chemical back extraction of actinides as chloride salts from the metallic phase to a salt phase containing AlCl_3 as oxidative species (Mendes et al., 2014).

Dimitrovgrad dry process

In the 1970–2000s, the Russian Institute of Atomic Reactors, RIAR, developed a pyroprocess allowing the recycling of MOX fuel from fast reactor and the fabrication of a mixed uranium oxide/plutonium oxide aggregates to be directly used in VIPAC fuel (Bychkov, 2009) (Fig. 18). With such a process, it is also possible to recover separately plutonium oxide and uranium oxide thanks to the different stability domains of the two oxides in the Pourbaix diagram.

The process was only demonstrated at the kilogram scale on spent MOX fuel (40 kg). So far, the DDP was mainly used to manufacture a few tons of MOX VIPAC fuel from a mix of pure civil and weapon grade plutonium and depleted uranium (7.2 t).

This process is very interesting because it combines all the potentialities of the chemistry in molten salt. First, the spent fuel is dissolved in molten salt by carbo-chlorination with uranium as UO_2^{2+} species and plutonium as Pu^{3+} . Then most of the uranyl cations are reduced as uranium oxide at the cathode under argon/chlorine atmosphere.

In the next step, it is possible to precipitate the plutonium as plutonium oxide by introducing oxygen gas in the Ar/Cl_2 atmosphere (DDP MOX $\rightarrow$ PuO_2 flow sheet). Then the remaining uranyl cations can be reduced again as oxide at the cathode.

Instead of precipitating the plutonium, by adjusting both the oxygen potential (by introducing oxygen in the atmosphere) and the electric potential, it is possible to deposit a mix of uranium oxide and plutonium oxide at the cathode (Fig. 19).

At the last step, the minor actinides and the rare earth are precipitated by sodium phosphate to purify the salt.

Good decontamination factors were achieved on different spent fuel samples (Fig. 20).

Liquid-liquid reductive extraction

An alternative to the electrolysis is the liquid-liquid reductive extraction developed at the CEA in the years 2000s (Conocar et al., 2005b). This process, operated in molten LiF-AlF₃ salt requires a dissolution of the spent fuel in the salt and is more relevant for oxide fuel reprocessing since the production of metal would require additional reduction processes. In such a salt, uranium, plutonium and americium are very selectively reduced into liquid aluminum thanks to the reductive properties of aluminum toward these elements in a bespoke contactor (Fig. 21). This is due to the specific activity coefficients of U, Pu and Am in Al. In one extraction batch, it is possible to recover 99% of Pu and Am with decontamination factors toward Ce and Sm higher than 250 (Fig. 22) (Conocar et al., 2006).

Once the pure actinides in the aluminum, they have to be back-extracted. This is possible by contacting the liquid metal with a molten chloride salt containing AlCl₃. The actinides are oxidized as AnCl₃ and transferred to the salt as cations (Mendes et al., 2012). They can be precipitated as oxide in order to re-manufacture fresh oxide fuel.

This route is less attractive for metallic fuel processing however, it could be suitable for nitride or carbide fuels.

In the first developments, the fuel has to be dissolved in the fluoride salt by fluorination using HF gas for instance. However, an innovative approach based on the Direct Solubilization Process (DOS) allows a direct processing of the solid oxide spent fuel (Mendes et al., 2016).

This process can also be used to reprocess CERCER transmutation targets (Mendes et al., 2016).

The key issue for developing an industrial pyroprocess

As shown in section “Current experimental feedback and key demonstration projects”, promising options have been developed up to the pilot scale but most of the developments have remained at the lab scale.

An international mobilization was observed between mid-1990s until mid-2010s but the effort has slowed down since then.

The main reason is the lack of industrial perspective for the development of fast reactors with metallic fuel worldwide, and more globally the lack of the development of advanced reactor fuel cycles. There is no clear perspective in Japan, a stop of the program in Korea, the selection of MOX pellet fuel for BN800 in Russia.

A renewal of pyrochemical process development could come from the molten salt reactors. However, the thermodynamics is not favorable since it imposes that first the actinides are removed from the salt before removing the lanthanides, which makes the process flowsheet complex. In addition, the programs led by US or Canadian start-ups focus on concept without processing, or with the minimum level of salt polishing. Moreover, concepts based on chloride salts could easily rely on an aqueous processing.

Finally, today, pyrochemical processes are far to be industrially deployed. Those addressing oxide fuels do not bring real benefit compared to aqueous separation processes, not to say ore drawbacks, in particular in terms of waste management and technological challenges (high temperatures, material corrosion, etc.). If the liquid-liquid reductive extraction core process is efficient and very compact, the whole flowsheet would be much more complex.

However, an opportunity could come from very specific and refractory transmutation targets that would hardly dissolved in aqueous media and therefore not suitable for such processes.

Pyroprocesses addressing metallic fuels could be deployed if a fleet of fast reactors operated with metallic fuel would be deployed. No plan exists today. However, in such a case more efforts should be put on the whole fuel cycle design “from fuel to fuel,” not only focusing on actinide purification and recycling, but also on all the ancillary steps that make a process viable salt fabrication and purification, maintenance, plant operation, analytical techniques and monitoring, material resistance and corrosion control. However, as minor actinides can hardly be separated from plutonium, such processes would lead to a homogeneous recycling strategy. For heterogeneous recycling strategies, in particular involving the sole recycling of americium, aqueous reprocessing would be needed even for metallic fuel, which reduces the interest of pyrochemical processes in this case (Poinssot et al., 2017).

The implementation of PUREX process at the industrial scale

Process steps

The purpose of fuel treatment is to recover reusable material (uranium and plutonium), with a level of purity compatible with the recycling operations, and to minimize and condition waste arising from non-reusable spent fuel components (fission products and minor actinides, but also metallic structures). To that end, very high recovery rate ($> 99.5\%$) and decontamination factors ($> 10^6$) must be achieved.

Current reprocessing plants use variants of the PUREX process. The main part of this process is based on hydrometallurgy, where a selective solvent, tri-*n*-butyl phosphate, is used with nitric acid in liquid-liquid extraction steps to recover reusable materials (uranium and plutonium), and condition the rest of the spent fuel (fission products, minor actinides, and fuel metallic structural elements) as waste. Process steps are hence organized to dissolve the material, then recover and purify the products. Those products are sent to recycling plants. Liquid effluents arising from those operations are treated before release or solidification, and waste are conditioned (Fig. 1).

Fuel receipt and storage

The very first step is to receive the spent fuel from the nuclear power plant or an interim storage and transfer it to the pool. The fuel assembly being transported in heavy transport casks, the task at hand is to open the cask, unload the fuel, transfer the fuel to the

Fig. 1 Fuel Treatment Process Steps.

pool, while managing irradiation and contamination risks from very active nuclear fuels. Additional operations are required to verify the identity of the fuel received, through visual observation of the fuel identification plate and nuclear measurements.

Two different unloading processes can be used.

- Underwater unloading is similar to what is performed at a nuclear power plant. The transport cask is opened under water, water providing both irradiation protection and cooling. The fuel is lifted with a crane, transferred to a basket and moved to the pool.
- Dry unloading on the other hand requires a docking station, and the transport cask design must be compatible with this docking station to provide a leak tight confinement when the cask is opened. The fuel remains dry until it is lifted down to a control well or to a basket for storage in the pool. Irradiation and contamination protection rely on the concrete walls of the unloading cell and the leak tightness of the docking station.

Dry unloading provides distinctive advantages. The contaminated inside cavity of the transport cask does not come into contact with large volumes of water, limiting the generation of radioactive effluents. In addition, damaged spent fuel can be identified and encapsulated in a container to avoid contamination of the pool. However, this dry process is less flexible, since the fleet of transport casks must be compatible with the initial design of the unloading facility.

At the end of the unloading process step, the spent fuel is safely stored under water in the storage pool of the reprocessing plant. There, water is treated and cooled to maintain it at low contamination levels and close to ambient temperature to prevent evaporation. Production programs and contracts determine when the fuel is transferred out of the pool for reprocessing, with a typical total cooling time of about 5 years. Additional cooling time decrease the radioactivity of the fuel, limiting solvent degradation (see “Organic effluents management” section), and may help reduce dose rate and releases. However, with additional cooling time, more ^{241}Am form from ^{241}Pu radioactive decay, decreasing the energy value of plutonium and increasing long term radio-toxicity and decay heat of the waste.

Mechanical treatment and dissolution

The purpose of the mechanical treatment is to prepare the fuel for dissolution and separate parts incompatible with or detrimental to the downstream process.

For fuels with a magnesium cladding (Magneox fuels for example), the mechanical process objective is to remove (to peel) the cladding before dissolution, in order to avoid dissolution of large amounts of magnesium that would increase the amount of high activity waste. The metal rod is then transferred to the dissolver.

For UOX fuels from current light water reactors, the cladding is made from zirconium alloys, not soluble in nitric acid. The mechanical process objective in this case is to ensure nitric acid will selectively leach and dissolve the oxide material despite the insoluble cladding. To that end, the zirconium cladded fuel is sheared (chopped) into small pieces of a few centimeter long, called hulls.

During the shearing process, a hydraulic gag presses and holds the fuel while a hydraulic blade cut through the fuel rods. The hulls fall by gravity through a chute to the dissolver. Between two cuts, the blade is moved back, the pressure on the hydraulic gag is released, and the fuel is pushed forward a few centimeters, exposing that much to the next cut. Those steps are repeated until the whole fuel has been fully cut.

Head and bottom end pieces of the fuel can be separated and directed to metallic waste conditioning through a separate chute, depending on the design of the dissolver and its compatibility with those large pieces.

The dissolution reaction of UOX fuel in nitric acid is described by Eqs. (1) through (3):

The exact proportion of NOx produced during the oxidation of UO₂ depends on the acidity and temperature of the dissolution solution. NO is favored at low acidity, while NO₂ dominate at high acidity and high temperature:

where Eqs. (2), (3) are related through an equilibrium reaction between NO and NO₂:

Plutonium is dissolved according to Eq. (5):

The effective dissolution rate is controlled mainly by nitric acid concentration, temperature, and surface area. Nitric acid concentration is chosen in a range compatible with the following liquid-liquid extraction process step, typically at about 3 mol L⁻¹ after dissolution, with a uranium concentration of 200–250 g L⁻¹. To accelerate dissolution, dissolvers are heated. Dissolution temperature can be up to the boiling point of the dissolution solution, although high temperature favors the formation of precipitates containing MoZr. Surface area is favored by reducing the length of hulls, but doing so also increases the number of cuts to shear the fuel, and hence the time to process it. Hulls length of a few centimeters is classically used.

Dissolution has been initially implemented as a batch process (for instance in Magnox plant in UK, UP1 and UP2 400 plants in France). For efficiency reason, a continuous process is used in more recent plants (UP2 800, UP3, Rokkasho), with a continuous rotary wheel dissolver. The wheel is divided into baskets. Through the rotation of the wheel, each basket moves from a loading position, where it receives hulls from the shearing machine, to dissolution positions, during which the basket is kept submerged in boiling nitric acid solution, and finally to the unloading position where hulls fall towards the metallic waste treatment. The duration of the dissolution process can be adjusted through modifying the rotation speed of the dissolution wheel (Fig. 2).

THORP reprocessing plant presents an intermediate design, with three batch dissolvers working in sequence, fed alternatively through a movable chute. Each dissolver is equipped with a basket to recover and empty the hulls after dissolution.

Fig. 2 The rotary wheel dissolver (CEA, 2008). Courtesy CEA.

Fig. 3 Treatment of gases from shearing and dissolution.

Three streams come out of the shearing and dissolution step.

- The main process stream is the dissolution liquor, i.e. nitric acid having dissolved the oxide part of the fuel, containing uranium, plutonium, minor actinides, and fission products. Sparging is used to remove iodine from the solution, directly in the dissolver at the end of the dissolution (batch dissolution process), or in a subsequent process vessel (continuous dissolution process). Precipitates and metallic particles are separated, using for example a centrifuge. In a buffer storage tank, solutions are characterized to account for fissile material received in the reprocessing plant. After dissolution, uranium is present as uranyl nitrate U(VI). Plutonium is present as Pu(IV). Some Pu(VI) can coexist, especially at high acidity, or when using a batch dissolver, because of the low amount of nitrous acid at the end of the dissolution. Because of its lower extractability, Pu(VI) in significant concentration could lead to plutonium accumulation in the extraction system. Systematic analysis and, where necessary, sparging with nitrogen dioxide, ensure plutonium is almost entirely under Pu(IV), as required by the following extraction and purification cycle. The dissolution liquor can then be sent to the extraction and purification cycles.
- Hulls and end pieces, i.e. the zirconium-made metallic structure of the spent fuel, are solid waste. They are conditioned in drums filled with concrete (THORP and initial La Hague design) or compacted (La Hague UP3 and UP2-800) to reduce the waste volume.
- Gases from shearing and dissolution contain nitric oxide and nitrogen dioxide produced during the dissolution reactions. They also contain small droplets of dissolution solution entrained with gases, and volatile fission products, especially ^{85}Kr , ^{129}I , ^{14}C , ^3H , and must be treated before release (see Fig. 3). Gases are first contacted with nitric acid and water solutions in washing columns. NOx are recovered as nitric acid. Droplets of radioactive liquid, including most of tritium present as tritiated water, are captured. Tritium is ultimately diluted into the sea in a high current zone, with distillates of the tritiated acid recovery unit (see below).

Gases are then contacted with caustic soda to capture ^{14}C present as CO_2 , and iodine present as I_2 . High efficiency filters and sorbents finally capture remaining traces of non-volatile material and iodine.

Captured ^{14}C can be either stabilized with concrete, and then stored (Sellafield, UK), or neutralized and released to the sea (La Hague). Captured ^{129}I can be precipitated and conditioned as solid waste (Rokkasho), or released to the sea (La Hague) where its radiological impact is low, thanks to dilution with natural iodine present in sea water.

^{85}Kr is a noble gas and as such does not interact with washing columns and filters. It is released to the atmosphere through a stack. Thanks to its chemical nature, its radiological impact to the population and the environment is low.

Detailed studies demonstrate that the effective dose potentially absorbed by people living near La Hague at $5 \mu\text{Sv yr}^{-1}$ for a fisherman at the nearby village of Goury and at $13 \mu\text{Sv yr}^{-1}$ for a farmer at the nearby village of Digulleville. Both villages were chosen as the most likely impacted nearby sites. Those estimates are consistent with IRSN estimates based on the results of environmental monitoring (IRSN, 2018).

Extraction and purification cycles

The PUREX process uses a solvent, tributyl phosphate (TBP), to selectively extract uranium and plutonium from dissolution liquor, separate then purify them. TBP forms complexes with uranium and plutonium, immiscible in water, effectively extracting those materials from the aqueous solution.

Reaching both a very high recovery rate and decontamination factors are seemingly contradictory objectives, as it means quantitative extraction of uranium and plutonium, and almost no fission product extraction, a level of solvent selectivity impossible to reach in single step. A succession of counter current liquid-liquid extraction steps are necessary to achieve the high level of uranium and plutonium recovery, and to purify them to the extent required by downstream fuel fabrication and recycling steps.

The solvent and the aqueous phase are separated using decantation. Because the density of TBP is very close to the density of an aqueous phase (0.979 at 25 °C, [Chemicalbook, 2021](#)), or even higher when complexed with uranium ([McKibben, 1975](#)), TBP has to be mixed with a light organic diluent, at 20%–30% vol. depending on plant design, ensuring an efficient separation of organic and aqueous phase. Addition of a diluent also decreases viscosity.

Industrial diluent can be odorless kerosene (Thorp reprocessing plant in the U.K.), hydrogenated polypropylene tetramer (La Hague in France) or n-dodecane (Rokkasho in Japan). Hydrogenated polypropylene tetramer is a highly branched 12-carbon alkane, with other C10 to C13 alkanes. It is the most resilient to third phase formation, a dangerous phenomenon where high concentration of plutonium or uranium induce an organic phase splitting, leading to diluent and a dense third phase of (U, Pu, TBP, HNO₃) ([Plaue et al., 2006](#)). The downside of hydrogenated polypropylene tetramer is a lower flash point, similar to n-undecane.

Extraction is sensitive to the following effects:

- Salting out: D_U increases with nitrate concentration in the aqueous phase
- Saturation: in consistency with Eq. (6), uranium extraction by the solvent is limited to 1 mol of uranium per 2 mol of TBP.
- Competition: U, Pu, H⁺ are all extractable, but saturation of the solvent by uranium will limit extraction of Pu, and H⁺
- Temperature: D_U decreases when temperature increases

where D_X is the distribution coefficient of component X, defined here as the chemical X concentration ratio between the organic and the aqueous phase.

For a given element, distribution coefficients vary greatly depending on the oxidation state, as illustrated in [Table 1](#). Solvent extraction and actinides separation in the PUREX process relies on the adjustment of the oxidation state of uranium and plutonium to separate those two elements.

The process to separate uranium, plutonium, and fission products, known as the first Uranium, Plutonium Cycle (1CUPu), implement those basic principles as illustrated in [Fig. 4](#).

In the feed of the extraction cycle, U(VI) and Pu(IV) are readily extractable, while most of fission products and minor actinides are not. In those conditions, uranium and plutonium are extracted by the solvent, while most fission products and minor actinides remain in the aqueous phase. A scrubbing operation removes fission products. Neptunium and traces of fission products (Ru, Tc...) still follow the desired products. To strip plutonium out of the organic phase, solvent is contacted with a reductant, uranous nitrate (U(IV)), stabilized with hydrazine (N₂H₄). Plutonium is reduced to Pu(III), non-extractable, and neptunium to Np(IV), extractable ([Fig. 5](#)).

Out of the plutonium stripping operation, the organic phase contains uranium and neptunium, while the aqueous phase has recovered plutonium. A uranium scrubbing step recovers U(IV) that could have followed plutonium and the aqueous phase. Plutonium solution is finally contacted with NO_x to decompose hydrazine and oxidize plutonium back to Pu(IV), ready for the second plutonium liquid-liquid extraction cycle (2CPu). Uranium is finally stripped, along with neptunium and traces of fission products,

Table 1 Valency states and extractability in TBP of uranium, neptunium, plutonium ([Guillaume et al., 1984](#)).

	Oxidation State			
	+III	+IV	+V	+VI
U		U ⁴⁺		UO ₂ ²⁺
Np		Np ⁴⁺	NpO ₂ ⁺	NpO ₂ ²⁺
Pu	Pu ³⁺	Pu ⁴⁺		PuO ₂ ²⁺

: Weak, good and excellent extractability

Fig. 4 TBP molecule $O=P(OC_4H_7)_3$.

Fig. 5 1CUPu: U, Pu and FP separation.

by contacting the solvent with a very low acidity aqueous solution while slightly heating the solution (around 50 °C). Uranium is then concentrated, ready for the second uranium cycle (2CU).

To reach the end-products specifications, an additional purification cycle is necessary, for both uranium and plutonium, with process conditions targeting the remaining contaminants.

- Uranium from 1CUPu is extracted again by TBP. A scrubbing operation removes traces of fission products still present (Ru...). Addition of hydrazine, a reductant weaker than U(IV), reduces neptunium to Np(V), but does not reduce it to Np(IV). Np(V), non-extractible, is stripped from the solvent. Final uranium re-extraction uses again the effect of temperature and low nitrate concentration to strip uranium from the solvent. Uranium is finally concentrated (up to 400 g L⁻¹) and turned into oxide before being sent to recycling plants.
- Pu(IV) from 1CUPu is also extracted again by TBP, while remaining contaminants stay in the aqueous phase. It is then reduced to Pu(III) using another reductant, a mixture of hydroxylamine nitrate (HAN) and stabilizing hydrazine (N₂H₄), and stripped back to the aqueous phase. The aqueous phase is contacted with NO_x to eliminate the reductants and oxidize plutonium to Pu(IV), ready for the conversion step.

Industrial implementation of the extraction cycles

The equipment used for the liquid-liquid extraction can be mixer settlers, pulsed columns or centrifugal extractor (Drain et al., 2003). All those technologies are used at different process steps, and different plants have different sets of extractors.

- Mixer settlers are simple to operate, especially during short shutdowns. They are very flexible and can accommodate a wide range of capacity. They have a large footprint. They can accumulate interfacial cruds. Because of usually large holdups, they may lead to

more solvent degradation due to radiolysis and hydrolysis. Extra-flat mixer settlers have been designed where subcritical geometry was required, but their capacity is limited. In the context of a reprocessing plant, and to provide protection from irradiation and contamination, mixer settlers are typically installed below a concrete slab. Motors for the mixers are installed above this slab, with a leak tight shaft going through the slab to link motors and mixers. That way, motors can be maintained and replaced when necessary without exposing workers to radiation.

- Pulsed columns with the right packing have low sensitivity to interfacial cruds. They can be designed with no moving part in radioactive areas: the liquid in the pulsation leg is pushed with compressed air, controlled with a valve located out of radioactive areas, and as such easily maintainable. Subcritical geometry can be achieved, even for relatively high throughput, with annular columns fitted with a neutron absorber shaft along the axis of the column. However they are high (up to 8 m), and need tall buildings to be installed in.
- Centrifugal extractors are mechanically much more complex, and therefore more sensitive to maintenance. Their main advantage is their compacity compared with the two other kinds of extractors. Their small holdup and residence time lead to lower solvent degradation. They are not tolerant to interface cruds.

For the 1CUPu, pulsed columns are usually selected, due to criticality constraints and the presence of interphase dross. For uranium cycle, with no criticality constraint and low irradiation risk, mixer settlers are preferred. For plutonium cycle, with high criticality constraints, centrifugal extractor or pulsed columns can be used.

To avoid the maintenance of mechanical moving parts contaminated by radioactive solutions, transfers use airlifts, ejectors, siphons, or just gravity, to the most possible extent, with control valves in non-radioactive areas. Pumps, when necessary, are designed with the motor above a shielding slab, and the core of the pump is such that it can be replaced using a shielded enclosure. Chemical equipment, with no mechanical moving parts, is installed in blind cells and is designed to last for the lifetime of the plant. Despite this initial design, equipment such as evaporators had to be replaced, due to corrosion.

Plutonium conversion

Plutonium conversion involves turning plutonium nitrate, coming from the extraction and purification cycles, into plutonium oxide (PuO_2), the required form for light water reactor fuel fabrication.

Plutonium nitrate is precipitated by mixing plutonium nitrate with oxalic acid. The plutonium oxalate slurry is filtered with a rotary filter and dried. Plutonium oxalic is then turned into plutonium oxide PuO_2 in an electrically heated screw calciner, at high temperature with an oxidizing atmosphere.

The key role of streams management and effluent recycling

Special care is needed during the plant design in order to reach high decontamination factors before release to the environment, and to minimize waste volumes. Aqueous effluents are sent to evaporators, where salts, including radioactive contaminants, are concentrated. Several consecutive evaporation and condensation cycles are necessary in order to minimize radioactive releases. To ensure the efficiency of waste management, effluents are sorted according to their radioactivity (presence or not of tritium, level of activity) and their chemical nature (aqueous, acidic or caustic, organic).

Aqueous effluents management and releases

Aqueous effluents treatments and nitric acid recovery

Acidic aqueous effluents arise from various plant operations: raffinates from extraction and purification cycles, water and nitric acid sent to gas washing columns, laboratory effluents, with activity levels from very high (raffinates from the first extraction cycle, containing all fission products and minor actinides from the spent fuels) to low (effluents from gas washing column of low activity parts of the plant).

Because of its mobility, tritium creates a contamination concerns where its concentration is significant. Therefore, the plant is divided into two broad areas, tritiated and non-tritiated parts. Tritium is present in significant concentration from dissolution down to the fission product scrubbing column of the first extraction cycle. Some tritium is extracted by the solvent in the form of tritiated water or tritiated nitric acid and could follow TBP to the non-tritiated part of the plant. The use of non-tritiated water and nitric acid for scrubbing solutions removes tritium from the solvent before it can reach the non-tritiated area. Each area, tritiated and non-tritiated, have their own aqueous effluents treatment and nitric acid recovery, forming respectively a tritiated acid loop, and a non-tritiated acid loop.

In the case of tritiated nitric acid recovery (illustrated in Fig. 6, actual plant design involving several evaporators running in parallel), the first evaporator receives the most active aqueous effluent, i.e. the raffinates from the first extraction cycle. It also receives concentrates from the medium activity waste concentration. Concentrates from this evaporator feed vitrification. Distillates feed the medium activity waste evaporator. The distillates of this second evaporator feed the tritiated acid recovery. Essentially a distillation column, the acid recovery concentrates nitric acid at ~ 10 M; concentrated nitric acid is recycled and is used to dissolve the spent fuel. Distillates from this column are analyzed to verify their remaining activity, then released to the sea. Tritiated water properties

Fig. 6 Principle of aqueous waste management, and tritiated acid recovery.

Fig. 7 Tritiated nitric acid loop.

being very close to the behavior of natural water, tritium is not concentrated in either of those streams, and is released with the distillates of the acid recovery unit (tritiated water).

All stable non-volatile salts added to the process end up in the concentrates of the high activity effluent concentration, and from there in glass canisters. Great care is taken to limit such addition; reagents are all made of C, H, O, N atoms, leaving at the end no residue (oxidized with NO_x or by concentrated nitric acid in evaporators), with the notable exception of caustic soda and sodium carbonate (Fig. 7).

The non-tritiated acid loop is similar in principle. However, the activity of the streams is very much different: received effluents come from areas of the plant downstream the fission product scrubbing, i.e. medium activity. Concentrates from the first evaporator is not sent directly to vitrification, due to its lower radioactivity, but is routed instead to the high activity evaporators of the tritiated nitric acid recovery.

Caustic effluents management

Solvent treatment use caustic reagents, caustic soda and sodium carbonates, to clean and recycle the solvent. Once used, those reagents generate caustic effluents. Caustic effluents from the first uranium plutonium cycle are concentrated in a specific evaporator. Distillates from this evaporator are released after control. Concentrates are conditioned as solid waste.

Organic effluents management

Tributyl phosphate sent to the extraction cycles is recovered after uranium stripping (or plutonium stripping, in the case of the 2CUPu). However, radiolysis and hydrolysis of TBP generates degradation products of the solvent (Fig. 8).

These degradation products are very detrimental to the purification cycles performance. They tend to stabilize emulsions. They can extract and maintain plutonium in the organic phase, even after the addition of reductants. Through the design of the plant and

Fig. 8 Main TBP degradation products.

operating rules, solvent degradation is minimized, trying to limit the time of solvent exposure to radiation and nitric acid. Solvent treatment is nevertheless essential for the lasting performance of the purification cycles.

Solvent sent to the extraction and purification cycles is recovered after plutonium or uranium stripping and is washed in mixer settlers with sodium carbonate and caustic soda reagents. This operation removes acidic degradation products and is enough to keep the solvent working. However, with this treatment alone, solvent must be entirely renewed after some time of service (years, depending on the expected performances), to retrieve acceptable performances.

An additional treatment, the Organic Waste Treatment (OWT), based on distillation, has been implemented at La Hague UP3 plant, then on UP2 800 and Rokkasho plant. Solvent is evaporated, and a distillation column separates diluent (the lighter phase), TBP, and a residue containing heavier degradation products and activity (Ginisty, 1991). Distillation is performed at low pressure and temperature, after washing the solvent with water to remove nitrates; otherwise, TBP would be degraded by excessive temperature and nitric acid, utterly defeating the purpose of this unit.

The combination of solvent treatment, using sodium carbonates and caustic soda, and organic waste treatment based on distillation has proved to be very effective at maintaining very high levels of decontamination factors and product purity achieved by the extraction cycles.

Another benefit of this unit is to produce a continuous stream of diluent (Fig. 9). This diluent is used to wash aqueous phase coming out of the extraction cycles, especially those going to evaporators. It extracts traces of TBP otherwise dissolved in the aqueous phase, improving downstream operations.

Used diluent is mixed with the process stream of solvent, effectively reducing TBP concentration below 30%. In the solvent treatment units, the operator adds TBP recovered from the Organic Waste Treatment unit to solvent, bringing its content back to the desired concentration. Keeping this TBP content within acceptable margins and controlling solvent flowrate to extraction cycles is critical for the good operation of the liquid extraction units.

The whole process, with the two complementary treatment, has kept the solvent in excellent conditions for 30 years. It also reduces the amount of waste, with a flowrate of residues equal to a few liters per hour.

Residues from the organic waste treatment unit are mineralized and conditioned as solid waste.

Fig. 9 Solvent management.

Buildings layout considerations

Nuclear risks to be addressed are contamination, irradiation, and criticality. Security of fissile materials requires access and material control. Flammable diluent and reactive reagents are used, so regular industrial risks are also present, such as fire risk, and chemical risks. Buildings are also designed to withstand earthquake, the magnitude of which being defined by the safety authority, taking into consideration historical and tectonic data, to allow for a safe shutdown of the facility and maintain desired confinement.

Initial reprocessing plants (Hanford, WA and SRS, SC in the USA) where built with a canyon type design, with a very long cell (more than 300 m long) housing the high activity process on one side, the medium activity on the other side. Along with versatile connection operated with a traveling crane, this design provides great flexibility. But with a more established flowsheet and emphasis on waste reduction and contamination prevention, individual process cells and welded pipes are preferred. Process cells and their concrete walls are meant to divide nuclear facility into areas with similar risks and constraints. They limit the spread of contamination in case of process leak and are designed to contain fire. Chemical process cells are organized around an “active gallery,” a large cell where pipes run from one cell to another, limiting concrete wall penetrations.

A typical chemical process cell, with no mechanical moving parts, is blind, with no maintenance planned for the life of the facility. They are fitted with drip trays, to detect and recover leaks, and air contamination level monitoring. Chemical equipment and pipes are welded, and chemical process cell contamination level is typically very low; contamination detection is often an early detection of a leak. Components requiring maintenance (pumps...) are specifically designed and fitted in process cells to allow for their replacement.

A mechanical process cell on the other hand is equipped with a range of maintenance tools: shielded windows for visual control, robotic manipulators for light maintenance and operation, traveling crane for heavy duty, and a super-maintenance system featuring a dedicated cell closed with a shielded door to maintain traveling cranes while being protected from irradiation. Because mechanical operations often involve breaching a confinement barrier (ex: shearing of spent fuel, or opening containers), contamination level can be high.

A key feature of a reprocessing plant is ventilation. Buildings are divided in successive zones, reminiscent of Russian dolls, from low contamination and irradiation risk (control rooms, changing rooms...) to higher contamination or irradiation risk (process cells...) located at the inner part of the facility. Control of non-contamination is mandatory when moving to a lower risk zone, to avoid spreading contamination to clean areas. Building ventilation, independent from process ventilation, is designed to sweep air from clean to more at-risk areas and regulate pressure differences accordingly. Process equipment is always at lower pressure than the surrounding cells. Air is filtered before release through building and process ventilation stacks, and contamination is monitored. Air contamination inside the buildings is continuously monitored through air sampling. Local and centralized alarms inform the personnel of any abnormal situations.

Ventilation is designed to mitigate the risk of fire, selectively shutting down air flow when and where necessary. It is also a preventative feature, meant to avoid the accumulation of potentially dangerous substance, such as hydrogen. Because of all the essential functions of ventilation, it is one of the few systems designed to always stay in operation, with the proper ventilator redundancy and proper power back-up.

Buildings are designed of course to accommodate process equipment. For example, the choice of pulsed columns for the extraction leads to tall buildings to house 8-meter-high columns. But buildings' size and process layout are also a consequence of selected transfer technologies. To avoid moving mechanical parts in contact with radioactive material, transferring by gravity, siphon or airlift is preferred to using pumps, when possible. This has a direct impact on possible relative elevation and maximum distance of process vessels.

Remote control and monitoring

Remote and automated operations are very effective at reducing operator exposure to contamination and irradiation. Therefore production activities are for the most part monitored and operated from centralized control rooms, except for maintenance activities and monitoring rounds, so much so that visitors are often surprised not to see any operators in the facility during their tour.

For safety reasons, the control system is organized in three independent systems. The mission of the first system is to pilot industrial production and to monitor the plant, just as any regular industrial process control system would do. It is supplied by the regular electrical grid. A second system is designed to bring and maintain the facility in a safe shutdown state when the first control system fails. From there, operators are able to control essential ventilation and refrigeration systems. Fire, contamination and irradiation monitoring is available. Onsite electrical generators and batteries supply electricity to the control system and local actuators. Finally, a third system is designed to control critical systems to avoid unacceptable consequences in accidental situations.

Many sensors used in the plant to feed the control system with data had to be developed or adapted to accommodate the high level of activity in the reprocessing plant and be virtually maintenance free. For example, bubbling rods are used extensively, to measure pressure, density, and volumes of solutions in tanks. In addition, specific nuclear measurements are implemented to measure plutonium concentrations or to characterize solid waste.

Analysis are often required before authorizing transfer of solutions to downstream process steps. Accountancy of fissile material before extraction cycles is just one example. Buffer tanks are thus necessary to keep the plant running while solutions are analyzed, and they significantly impact building volumes. With the development of online chemical analysis capabilities, it is tempting to

replace those buffer tanks by online analytical systems whenever possible, with an expected benefit on initial investment cost. However, those buffer tanks also provide flexibility and improve the overall reliability and availability of the plant, by decoupling otherwise continuous process steps.

Short industrial feedback from worldwide commercial plants

<i>Reprocessing plants</i>	<i>Design capacity</i>	<i>Start of operation</i>	<i>End of operation</i>	<i>Maximum annual production</i>
UP3 & UP2-800	1700 t yr ⁻¹	1989–1994	–	1700 t yr ⁻¹
THORP	1200 t yr ⁻¹	08/1997	11/2018	900 t yr ⁻¹
Rokkasho-Mura, JP	800 t yr ⁻¹	Supposed to be in operation in 2022	–	–

UK

THORP (Thermal Oxide Reprocessing Plant) is a nuclear reprocessing plant located in Cumbria, England, on the Sellafield nuclear site. Design capacity was never reached, and the plant suffered several outages, most notably about 3 years due to the 2005 leak of 83 m³ of dissolution liquor in the feed clarification cell ([Health and Safety Executive, 2007](#)). Failure to reach production targets led to economic difficulties. Decision to shut down reprocessing operations was taken in 2012. Reprocessing operations ended in November 2018, after fulfilling existing reprocessing contracts.

France

UP3 (Uranium Plutonium 3, names after older plants UP1 and UP2 in France) was built to treat nuclear spent fuels from Germany, Belgium, Switzerland, Italy, Spain, the Netherlands and Japan and started operation in 1989. Compared with previous plants, several major innovations were introduced, including the shearing machine, rotary wheel continuous dissolver, and the Organic Waste Treatment. Aqueous effluent treatment was initially partially based on a precipitation process, precipitates being then mixed and solidified with bitumen. After a very successful start-up of the plant, performances were found to be better than their design value. A new aqueous effluents management was implemented, with the construction of several additional evaporators, leading to the process presented above, reducing the volume of waste and cutting radioactive releases of the plant. Corrosion issues have forced the replacement of several evaporators before their designed end of life. The operator (now Orano) was able to replace them, demonstrating its capacity to modify and retrofit those plants.

UP2-800 started operation in 1994 and was built to reprocess spent fuels from French nuclear power plants. Its process is almost identical to the UP3 process, although the plant layout is very different due to site constraints and start up strategy: UP3 was built from scratch, while UP2-800 facilities were replacing older, UP2-400 equivalents, over a 10-year period.

The two plants combined throughput reached 1700 t yr⁻¹ in 1996. Since then, and with many of its foreign customers reconsidering their nuclear policy or having decided to phase out of nuclear, production has fallen to about 1200 t yr⁻¹, most of it for the French utility EDF. Its design capacity would be difficult to reach again: the plant was initially designed to reprocess spent fuels with burn-up close to 33 GWd t⁻¹, currently reprocessed fuels are now at 45 GWd t⁻¹, with proportional amount of fission products and above proportional amount of minor actinides.

Japan

Rokkasho reprocessing plant in Japan uses technologies from France (UP3), the U.K. (THORP), and technologies developed in Japan. The successful UP3 design was used extensively, with the notable exceptions of the high-activity liquid waste concentration unit, based on THORP design, and the vitrification facility, based on Japanese technology developed in the Rokkasho reprocessing plant. Another significant difference is the management of iodine, released to the sea by other reprocessing plants. Instead, iodine is captured by solid sorbents. Started in 1993, its construction and commissioning suffered several delays. Active tests, using actual nuclear spent fuel, started in 2006. New safety standards enacted after the 2011 Fukushima accident have further delayed the start of operation, now expected in the first half of FY2022.

Cost of reprocessing

The cost of reprocessing and of nuclear waste final disposal is the subject of public debate trying to compare spent fuel management options, i.e. reprocessing and direct disposal. The purpose of this section is to present key findings and conclusion of the study published by OECD on this matter ([OECD, 2013](#)).

- Spent fuel management is a small fraction of the total cost of electricity (about 7 USD MWh⁻¹). However, the absolute cost can be large, depending on the size of the fleet.
- The difference of the total fuel cycle costs between the options considered are within uncertainties (see Fig. ES.1 p16 of the report).

Those results are sensitive to the discount rate accounted for in the estimate. Higher discount rates decrease the contribution of future expenditure, and tend to favor open cycles, with no upfront investment in a reprocessing plant.

With a relative neutrality of the economic argument, the report stresses the ultimate importance of qualitative parameters in the decision-making process, such as security of energy supply, non-proliferation, public attitudes, environmental effects, wastes streams, and perspective of development of advanced fuel cycles.

Poinssot (2014) compares environmental impact of open fuel cycle and mono recycling, and concludes that an open cycle has a bigger environmental impact, spending more natural uranium (+16%), and producing higher volume of high level radioactive waste.

The rationale and properties of MOX fuels

Rationale for recycling

Development and energy consumption are strongly associated. Energy experts estimate that the demand for primary energy in the world will increase approximately 65% by 2030, and the demand for electricity will double. Correspondingly, the progressive rise in average temperatures as well as Greenhouse gas emissions produced by human activity directly affect global warming and are specifically due to the burning of fossil fuels. Nuclear power is used to generate electricity for base load production free of all external constraints, and with zero greenhouse gas emissions. It is a definite advantage in the fight against global warming. Meeting energy needs, and environmental issues are key challenges and nuclear power constitutes part of the solution especially with its recycling concepts and designs. The objective of this article is to explain the industrial mono-recycling of Uranium and Plutonium in a closed fuel cycle. It is based upon a proven track record of recycling nuclear materials and has already achieved significant savings of earth resources to produce efficient and carbon-free energy. Recycling the energy from used fuel and efficiently managing the waste are key factors for sustainable growth of nuclear energy, bringing lower volumes and radio toxicity of waste, an enhanced proliferation resistance, uranium savings and economic benefits (Poinssot et al., 2016; Nuclear Energy Data 2007, 2007).

Why recycling?

Up to 96% of used nuclear fuel is recyclable. When unloaded from the reactor, the used nuclear fuel contains about 4% of fission products and minor actinides and an estimate of 96% of valuable materials (fissile and fertile materials), as demonstrated in detail in previous sections of the present document and shown in Fig. 1 below.

Recycling used nuclear fuel is interesting for recovering valuable materials, and it is equally a responsible solution for managing nuclear waste.

The purpose of recycling is thus twofold:

- 1) To recover energy from valuable materials as the spent fuel still contains U and Pu;
- 2) To separate the actual waste from valuable materials and to condition them into a safe and compact form suitable for transportation, storage, and final disposal.

The recycling principles

Recycling has been implemented in several countries for more than 45 years, with 40+ reactors using MOX (Mixed Oxide Fuel) fuel with an excellent return of experience. MOX fuel can be defined as the mixture of uranium and plutonium oxide fuel (Fig. 2).

Recycling of nuclear used fuel is a proven industrial process which allow the re-use of uranium and plutonium into new fuels: Enriched Reprocessed Uranium fuel (ERU fuel) and Mixed Oxide fuel (MOX fuel). At the end of the process, both recycled materials (either in the form of fresh fuel assemblies like MOX and ERU fuels or in the form of oxide powder ready to reuse in the case of uranium) and the conditioned waste are returned to the customer (Spent Fuel Reprocessing Options, 2009).

The benefits of recycling

Recycling offers immediate benefits to utilities. Recycling period and duration is a great benefit for utilities: between the unloading of used UO_2 fuel from the reactor and the loading of the fresh recycled fuel assemblies, the length of time is typically 15–20 years. Moreover, recycling globally allows a significant reduction of the quantity of spent fuel in storage pools. The volume reduction is as follows: 8 spent UO_2 fuel are used to produce one fresh MOX fuel, and one fresh ERU fuel through enrichment of Reprocessed Uranium (RepU). So, recycling offers an immediate and efficient mean for utilities to optimize their storage needs and avoid the accumulation of large quantities of spent fuel.

Spent fuel assembly

Fig. 1 Used fuel assembly and its recyclable material ratios.

Fig. 2 Nuclear fuel closed cycle.

For example, in France without recycling the used fuel stockpile would reach more than 50,000 tons by 2030. With recycling, this stockpile has been stabilized to about 15,000 tons, and could be reduced further if needed, depending on the strategy chosen by the French utility (for instance, to prepare the feeding of future fast reactors).

Advantages of recycling

Recycling produces energy

Each MOX Fuel Assembly (FA) in current Light Water Reactors (LWRs) supplies about 50,000 Tons of Oil Equivalent (TOE) in energy. This corresponds to the electrical annual consumption of one European city of about 100,000 inhabitants.

Recycling saves resources

Recycling enables up to 25% in natural uranium savings. The comparison is based on the amount of enriched uranium which is needed to produce 100 TWh of electricity in closed (with recycling) and open cycle (without recycling). Without recycling, 280 tons of enriched uranium are necessary, while this quantity can be reduced to 215 tons with recycling, thanks to the additional power brought by using MOX and ERU fuels. Final waste is reduced to the minimum, in the closed cycle, only non-reusable materials are considered as actual waste, and are conditioned for final disposal (Fig. 3).

Recycling favors nuclear acceptance

Without a solution for the management of radioactive waste, the percentage of favorable opinions for nuclear energy is 44% but increases up to 62% with a solution for waste management. By offering a sound and efficient solution to saving earth's resources and waste management, recycling is clearly well-perceived by the public (Barbat and Liberge, 2013, pp. 78).

In addition, proliferation resistance is enhanced by recycling:

- continuous reuse of fissile material for light water reactor or fast reactor.
- no need of safeguarding HLW (they do not contain any significant quantities of plutonium).

Principles and industrial feedback of MOX fabrication

Principles of MOX fabrication

In enriched uranium, the fissile material is inherently present in the fuel. For MOX fuel, the fissile material which is plutonium must be added to the carrier material uranium. Precipitation of plutonium oxalate is the most widely used commercial process for obtaining plutonium dioxide for MOX fuel fabrication, and this technology has reached an advanced level of maturity. It is performed in the treatment facility which can be combined or separated from the proper MOX fuel facility. Three options for carrier material have been investigated for commercial plutonium recycling strategies: natural uranium (U-235 at 0.8%), depleted uranium (U-235 at 0.2%) or reprocessed uranium separated during the treatment of used fuels. Early designs were based on natural uranium. Reprocessed uranium has also been used in test MOX fuel assemblies demonstrating its general suitability as a carrier material. However, the isotopic composition of the reprocessed uranium is mainly dependent on the initial enrichment and the burnup of the used fuel. As a consequence, this will greatly complicate the design and plutonium content of the MOX fuel. Those two materials are not in use anymore and current MOX is fabricated mainly with tails depleted uranium as the carrier for economic reasons. Since MOX fuel assemblies are more expensive to fabricate than UOX uranium fuel assemblies, there are economic incentives to concentrate as much plutonium in the assemblies as possible. This blending of two fissile/fertile materials is the most specific difference between uranium and MOX fuel manufacturing. Plutonium has an energetic, radioactive behavior including alpha, beta and gamma radiations and it must be separated from the environment, the workers, and the public. All production operations must be conducted in strict confinement using glove-box technology and automated processes (Figs. 4 and 5).

Fig. 3 Closed cycle savings of uranium due to MOX and RepU use.

Fig. 4 Example of a simple glove-box.

Fig. 5 Three barriers concept.

The first fabrication processes appeared in Germany, France, USA, UK and Belgium in dedicated fabrication plants. Each plant was characterized by specific processing approaches, and influenced by their design basis as well as their licensing limits:

- Isotopic composition of plutonium allowed
- Maximum americium content
- Maximum plutonium content in the MOX fuel
- Maximum allowed personnel exposure
- Confinement rules
- Criticality approach

These parameters greatly influence the equipment adopted, the plant size, and the plant layout.

In USA a few pilot fabrications started in the early 1960s but never attained industrial status.

The first fabrication plant in Germany was in Hanau for the SIEMENS company it operated for FBR and PWR fuels but was shut-down prematurely in the early 1990s by the green party.

In Belgium the plant was operated by BELGONUCLEAIRE in Dessel and developed the first two-steps process.

In France the plant named COGEMA Cadarache was the largest FBR Fuel plant, it then enters in transition to PWR fuels in the 1991 until it stopped of operation after 2010 to be replaced by the more industrial MELOX plant.

In the UK a plant named MDF (MOX Demonstration Facility) was a predecessor to a bigger facility named SMP (Sellafield MOX Plant); both facilities were shut down in 2011.

The conventional fabrication route is a direct application of the most common industrial process used for uranium fuel, the enrichment of uranium being replaced by a mechanical blending of the feed powders: UO_2 and PuO_2 and $(\text{U}, \text{Pu}) \text{O}_2$ for the scrap recycle material.

Three main processes were used:

In the 1970s the French CEA developed the COCA process in its Cadarache facility. It is an acronym for Cobroyage (co-milling) Cadarache and it is based on an optimized ball mill acting as a blender. The powder is then forced through a calibrated sieve to produce a free flowing granulate, adequate for feeding the rotary pellet press. This process was originally developed for Fast Breeder Reactor fuel. It eventually became adapted for PWR MOX fuel.

During the 1980s in the UK, BNFL developed a process named Short Benderless Route (SBR), which is based on the application of alternative process equipment for blending and granulation functions. The ball mill is replaced by an attritor adapted for providing a short processing time. The precompaction granulation is replaced by a spheroidizer equipment working on a powder agglomeration principle.

Today's most common process is the MIMAS (MIconization of a MASTer blend). Invented in the early 1980s, it is an adaptation of earlier fabrication processes that involved a single blending step.

Furthermore, the process evolved into a two blending step process. This evolution occurred when industrial production started to ramp up. The process developed due to the increase of specification demands from the fuel designers, fuel users in the Nuclear Power Plants, and even treatment facilities of spent fuels (Fig. 6).

In the first step, the pure PuO_2 feed and some UO_2 are co-micronized resulting in a master-mix of UO_2 - (typically 30% PuO_2). In the second step, the master mix is blended down with free flowing UO_2 to the specified content of the MOX fuel. Pelletizing is carried out in hydraulic presses with multiple dyes for increased productivity. Sintering is most commonly conducted in continuous electric powered furnaces. The pellets are arranged in large Molybdenum boats and then pushed sequentially inside the furnaces where their temperature will ramp-up to 1750°C after a 24-h cycle in a specific atmosphere. The very close contact between the micronized UO_2 and PuO_2 particles provides for adequate interdiffusion of cations during sintering and therefore the achievement of the required level of homogeneity. Centerless grinding is then performed in dry conditions to adjust very precisely both diameter and perfect cylinder shape of the pellets. Following a visual and dimensional inspection, all conforming pellets are placed on specific trays in order to weigh them. Then the preparation of pre-measured lengths of the pellet columns are ready to be introduced in zircaloy tubes named rods. Pellet samples are randomly sent for various analyses in laboratories for Quality Control (QC).

Fig. 6 MOX process using a two-step blending.

Tungsten Inert Gas (TIG) welding is commonly adopted for both the circular weld and the seal weld of the upper end plug of the rod. The seal weld is closed after the introduction of a pressurized helium gas into the rods. After their fabrication, the MOX fuel rods are inspected and tested for their integrity, the quality of their welds, their leak-tightness and overall conformity to the required specifications. Then later being sent to a rod storage, fuel rods of different and adequate Pu contents will be positioned in magazines with the same lattice of the Fuel Assembly (FA). The rods will then be drawn automatically and layer by layer pulled from the magazines through the Fuel Assembly skeleton. The Fuel Assembly (FA) manufacturing and Quality Control (QC) are fully automated and are identical to the UOX Fuel Assembly manufacturing. After storage, to constitute a reload of a given campaign the MOX FAs are handled and placed in dedicated and specific shipping containers before their transportation to the nuclear reactor. MOX FAs can be transported by ship, railway or road to reach their destination (Garwin et al., 1994).

Industrial feedback of MOX fabrication

The technologies of recycling and fuel fabrication have been adapted for plutonium recycling for more than 45 years. Since, plutonium recycling has been focusing on the stabilization of the separated plutonium inventory. Currently, the use of MOX fuel has been established on an industrial scale in a number of countries. In Germany, Belgium, France, Netherlands, Switzerland, and Japan a considerable number of thermal power reactors, both pressurized water reactors (PWRs) and boiling water reactors (BWRs), are either licensed or a license has been applied for. A license is required in order to use MOX fuels at levels up to 30% or more of the reactor core.

The number of "MOXed" reactors is the following:

The "MOXed" reactors represent 10% of the world's nuclear reactors. In Germany, the first loading of MOX fuel was in 1972, in Switzerland it was in 1984, in France it occurred in 1987, then Belgium and Japan in 1995 and finally in the Netherlands in 2014 (Fig. 7).

Ultimately, the industrial quality has been achieved and the performances of MOX fuel are equivalent to the performances of UOX. The MOX fuels have reached high burnup equivalent to UOX fuels (> 60 GWd/tHM) notably in Germany and Switzerland. The UK is investigating the incorporation of its 120 tons of reactor-grade plutonium into MOX fuel which would be used in LWR or CANDU reactors.

In the mid-1990s for disarmament purposes, plutonium from nuclear weapons declared in excess by USA and Russia was also considered for MOX fuel. Weapons-grade plutonium has over 93% of the fissile isotope, Pu-239, and can be used as well as a reactor-grade Pu, in fuel for electricity production.

Options considered for the disposal of weapons-grade plutonium included:

- Immobilization with high-level waste - treating plutonium as waste,
- fabrication with uranium oxide as a MOX fuel for burning in existing reactors,
- fabrication with thorium for existing reactors,
- fuel for fast-neutron reactors.

These considered options are now stalled or in stand-by.

The MOX fuels have presented a high reliability as they have shown no measurable impact on reactor operations (no early outage, no reactor shutdown, no material dissemination into primary water) for 45 years. The impact on the operation of the reactor caused by the very limited number of rod leakages is the same for MOX as for UOX and does not impose new constraints. The safety authorities in the countries operating MOX fuel in commercial reactors have determined that it is safe. The safety authorities have concluded that it meets the highest safety standards and the same rigorous licensing requirements as UOX fuels.

Fig. 7 Reactors having loaded MOX reloads.

MOX is also used in fast neutron reactors in several countries, particularly France and Russia. It was first developed for this recycling, with research and design being done in USA, Russia, UK, France, Germany, Belgium and Japan. Today, Russia has long-term plans to build a new generation of fast reactors fueled by MOX for the BN-800 fast reactor which started up at Beloyarsk, in mid-2014. France also has a long industrial experience with fuel for its PHENIX and SUPERPHENIX reactors, and may reconsider Fast Breeder Reactor (FBR) in the future.

The U recycling: Specificity of fuel fabrication from RepU

RepU Re-use and fabrication feedback

After the treatment of used nuclear fuel, there is the opportunity to fully close the fuel cycle by using the 95% remaining material in the form of reprocessed uranium or RepU. Utilities performing the reprocessing of used fuels are facing a growing RepU inventory, raising the risk of demonstrating an exit for this material. After fission products and plutonium (Pu) have been removed from spent LWR fuel, RepU remains.

A fissile content in the RepU of 235-U of 0.9% wt. to 1.1% wt., two possibilities are available: either direct use in certain type of reactors using natural uranium as the CANDU reactors or re-enrichment for reactors using enriched uranium as their fuel. It is to be noted that China is planning to use RepU in CANDU reactors that could be strictly devoted to this objective ([Use of Reprocessed Uranium, 2010](#)).

RepU in CANDU reactors

These reactors have a sufficiently high neutron economy to use RepU as fuel. RepU from spent LWR fuel can be considered as a lower cost source of enrichment at the optimal enrichment level for CANDU fuel pellets. In Europe the feedstock of RepU is approaching several thousand tons, and would provide enough fuel for numerous CANDU reactors for many years of operation. The use of RepU fuel offers significant benefits to CANDU reactor operators. RepU fuel improves the fuel cycle economics by increasing the fuel burnup, which enables large cost reductions in fuel consumption and in spent fuel disposal. RepU fuel offers enhanced operating margins that can be applied to increase the reactor power. These benefits can be put in place using existing fuel production technologies and practices. Additionally, these benefits can be established with almost negligible changes to fuel receipt and handling procedures at the reactor site. The application of RepU fuel could be an important element in many NPPs around the world. For example, China is contemplating the recycling of RepU on an industrial scale in the nearby future.

ERU in AGR and LWR

Starting in 1976 when the price of natural uranium was high, reprocessed uranium (RepU) recovered from Magnox fuel was re-enriched and fabricated into fuel for the British Advanced Gas-cooled Reactors (AGR). Over 15,000 tons of Magnox RepU was recycled to produce over 1500 tons of enriched reprocessed uranium (ERU) fuel for AGRs. The recycling ceased in 1996 as it became economically unattractive due to a combination of factors, such as low U-235 content of Magnox RepU (with increasing discharge burnups) and falling natural uranium prices.

Utilization of ERU in Light Water Reactors (LWR) began in the German Pressurized Water Reactor (PWR) Obrigheim in 1983, which was then followed in the late 1980s by Japan, France and Belgium. If not utilized, RepU constitutes a liability consisting in the costs of conditioning, interim storage and final disposal as a waste. As a result, in countries with political uncertainty about the future of nuclear power such as Belgium, Switzerland, Germany and the Netherlands, the utilities did recycle their ERU in the LWRs. Countries with a long-term policy of nuclear power generation, like France and Japan, store their RepU as a fissile material reserve. Recycling some of it as ERU is only applied on a reduced scale to ensure the availability and maintenance of the technology. For example in France, for many years, Electricité de France (EDF) has loaded ERU fuels in four 900 MWe reactor units at Cruas. France has a multi-decade experience in producing, managing and using ERU Fuel Assemblies (FA). The first implementation of reprocessed uranium (ERU) reconversion and fuel fabrication was achieved in the Romans, France facility in 1987.

Between 1987 and 2000 for each fabrication campaign, up to four « 900MWe » reloads per year, 20 tons of ERU each were produced. Around 1200 URE Fuel Assemblies have been loaded in 900 MWe Cruas reactors, leading to the saving of 4500 tons of natural uranium. The lessons learned from reactor operations are excellent and ERU fuel behavior was identical to natural uranium. The ERU recycling stopped in 2013, but will start again in 2023. EDF is evaluating the capacity of the industry to re-start ERU FA manufacturing for its 900 MWe fleet as well as for its 1300 MWe reactors. EDF will elaborate its schedule to manage all the needed upgrades and investments in the facilities for the industrial recycling of ERU. Although the experience with RepU and ERU from oxide fuel has been limited, there have been successful demonstration campaigns which will result in an increase in recycling in the future.

Fabrication challenges from RepU to ERU

The RepU contains only 1% wt. of U-235 and thus needs to be re-enriched in a dedicated facility to become Enriched Reprocessed Uranium (ERU) with an enrichment level similar of the Enriched Natural Uranium (ENU) close to 5%wt. First, the separated uranium is purified and concentrated, then the RepU is stockpiled in the form of stable oxides: U_3O_8 or UO_3 .

The RepU specificities are due to its isotopic composition:

- The level of U-235 is around 1%wt.
- Presence of U-232 (some ppb): its radioactive decay leads to gamma emitters with a risk of external exposure requiring biological protection or specific operating procedures
- Presence of U-234: alpha emitter and neutron absorber
- Presence of U-236: neutron absorber but no influence upon radioactivity emission

The fabrication route is as follows: The RepU in its oxide form must be converted to a gaseous state in hexafluoride of uranium: UF_6 . The process is fundamentally the same as for Unat, with the exception that the radiation shielding must be added, and the process must be operated faster. Thus, leading to significant over-cost. The enrichment facilities are designed to process UF_6 and can adjust to the UF_6 from RepU with few modifications. *Re*-enrichment of RepU will create 7/8 of depleted RepU with no possibility to be recycled in the current nuclear fuel cycles. After enrichment to the targeted U-235%wt. content the UF_6 must be reconverted into an oxide form in a reversion facility. The daughter products of the U-232 remain in the waste stream after the last gas vaporization. It authorizes the reduction of dose rate exposure and facilitates the handling and transportation of containers with RepU solid heels. The freshly produced UO_2 powder is therefore free from these daughter products. However, from the date of vaporization, the relatively fast decrease of the U-232 leads to the reappearance of those daughter products in growing quantities. As a result of this process, the product is named Enriched Reprocessed Uranium or ERU.

Fuel fabrication plant

The beta emission of U-232 is about 10% higher for the ERU than for the ENU. Also, the daughter products of U-232 will emit harmful gamma rays. Usually, fuel plants are limited to a U-232 of less than 15 ppb; and therefore need special licenses, specific environment requirements and protective equipment for the workers to operate with U-232 of around 20 ppb or more. Capital Expenditures (CapEx) for protective equipment and production management are needed as well as an increase in Operational Expenditures (OpEx). The fuel fabrication plant needs to be able to master the speed of the process, and the manufacturing steps to decrease the ageing of U-232 (and daughter products). The fuel fabrication plant must also be able to manage ERU FA manufacturing in parallel with ENU FA manufacturing. To avoid gamma dose rate increase, it is also key to limit the time the ERU spends in the installation. In order to avoid ageing, it is essential to supervise the time the material spends in storage and to detect zones prone to accumulation.

Properties of MOX fuels

The neutronic design of MOX assemblies is based on the simple principle that the assemblies must be equivalent to assemblies containing only uranium fuels in terms of power generated, overall reactivity and accumulated burnup. The MOX fuel must meet all safety criteria in manufacturing, transportation, handling, storage and reactor operation. It must also meet all safety criteria, concerning the unloading and later reprocessing of the used elements. As the current operation in reactor is mainly made in hybrid cores (i.e. MOX and UOX fuel together), it must provide no impact on the UOX fuel assembly design. For good handling and compatibility, the mechanical structure is identical to UOX assemblies thus enabling no impact on reactor design and limited impact on core operation. An additional goal for MOX fuel is to reach the same level of recyclability and used fuel management to meet equivalent economic criteria.

To fully understand the properties of MOX fuels, we must compare them with UOX fuels. During the in-core evolution, the fuel undergoes physical and chemical transformations related to the fission reactions and high temperatures endured. MOX and UOX fuels behave in slightly different ways which consequently influences performance and key safety parameters ([Status and Advances in MOX Fuel Technology, 2003](#)).

Isotopic evolution

The MOX fuel contains plutonium fissile isotopes; Pu-239 and Pu-241 generate more fissions than the U-235 present in the UOX fuel. However, Pu-240 is also present in the fresh MOX fuel; it features a very high neutron capture cross-section, higher than the cross-section of U-238 present in UOX fuel. During the in-core operation, the evolution is that Pu-240 inventory is decreasing and thus its related capture properties also decreases with the burn-up. This results in an increase through absorption of the Pu-241 inventory and an increase in additional fissions. It is also to be mentioned that during irradiation Pu-239 is generated in both MOX and UOX fuel from neutron capture by U-238 and is consequently contributing to additional fissions along the reactor operation ([Figs. 8 and 9](#)).

Reactivity

The plutonium composition has an impact on time-dependent neutronic behavior of the MOX fuel. The reactivity of MOX fuel decreases more slowly with burnup than that of UOX fuel. At a higher burnup, MOX fuel generates more power than UOX and experiences a higher transient power for the same increase in neutron flux than equivalent UOX. The MOX fuel presents a harder neutron spectrum based on its energy distribution. For their use in hybrid cores, the design of MOX assemblies has therefore been

Fig. 9 Isotopic evolution in MOX fuel.

optimized to reduce the power peaking at the uranium/MOX interface and as a result has been designed to obtain the flattest possible power distribution (Fig. 10).

This is achieved by zoning the assembly, using three plutonium enrichments (or content zones) in a concentric distribution as shown in Fig. 4 for a PWR fuel assembly.

Thermal behavior

Due to the difference in the pellet composition and structure, MOX fuel possesses different thermal conductivity than UOX. At lower temperatures (below 1200 °C), the thermal conductivity is about 10% lower than of UOX. This leads to different temperature profiles within the fuel and a higher central line temperature for MOX at an equivalent power level. At higher temperatures, the difference reduces. Another thermal characteristic is the melting temperature of the pellets. MOX and UOX melting temperatures are equivalent (higher than 2750 °C) and far above the maximum pellet temperature in the core during normal operating conditions (typically maximum is 800 °C). There are also differences between MOX and UOX in terms of decay heat released after discharge; this is mainly due to the difference in actinides inventory. Just after the end of the chain reaction, decay heat is dominated by delayed neutron fission (which inventory is lower in the case of MOX fuel) and the contribution of short-lived Fission Products (FP). In the hours after shutdown, the decay heat released by MOX is lower than the decay heat released by UOX. Although in the long term, the MOX will still generate more heat due to a difference in actinides inventories resulting in relatively slow decay in comparison to Fission Products decay. The decay heat is dominated in the very long term by Am-241, Pu-239 and Pu-240 for which the inventories are larger in the case of MOX (Figs. 11 and 12).

Fig. 11 Comparison of fuel temperatures in relation to burnup.

Fig. 12 Heat decay of different types of fuel.

Physical and chemical properties

For both fuels during the in-core evolution, the pellets will undergo physical and chemical transformations relating to the prevailing high temperatures and fission reactions.

The following phenomena will occur:

- **Densification:** it will happen during the early stages of reactor irradiation, caused by disappearance of submicron pores. The densification behavior of MOX fuel is comparable to that of UOX fuel.
- **Swelling:** After the initial densification, a new phase will occur, the swelling due to the accumulation of Fission Products. The gaseous swelling kinetic is slightly different in MOX fuel than in UOX because of the difference in fission gas release of the two fuels.
- **Fuel Creep:** Creeping is the process that causes the cladding material under constant load to deform progressively. The creep rate in fuel is dependent on several parameters including temperature, fission rate, grain size... Accordingly, MOX and UOX feature different behaviors regarding creeping. Higher creep rates in MOX fuel, enables the relaxing of the cladding stress more quickly.
- **Pellet Cladding Interaction (PCI):** It is a complex phenomenon that tends to occur under power ramping conditions in the reactor. The expansion of the fuel pellets due to high internal temperatures, cracking due to thermal stress, and irradiation induced-swelling may lead to mechanical interaction of the fuel with the cladding. In extreme conditions, PCI may lead to cladding failure and disturb the reactor operation. The MOX fuel presents better results in PCI resistance due to enhanced creep rates of MOX as compared to UOX.
- **Fission Gas Release:** The Fission Products resulting from the fission of uranium or plutonium are the same regarding their type, however they differ in their repartition. The non-volatile are embedded in the pellets and are equivalent for both fuels. The volatile ones are in equivalent production quantity but of different types and it is important as they are the major contributor in case of the very unlikely event of an accidental release. In regard to the noble gases, the contribution for MOX fuel is higher toward the higher burnup and leads a higher internal pressure. The MOX fuel rod design integrates this specificity of higher internal pressure by a bigger plenum volume inside the rods to safely accommodate the gas release.

In conclusion, the properties and differences in fuel performances between MOX and UOX may lead to:

- higher MOX centerline temperatures,
- specific microstructures in the Pu-rich agglomerates (Fig. 13)
- greater fission gas release and,
- higher rod internal pressure.

These differences are relatively minor and manageable, falling within fuel design margins. Furthermore, MOX fuel features a higher potential for energy production due to higher production of neutrons from fissions in one generation (Figs. 14 and 15).

Overview of the overall cost associated to U/Pu recycling in MOX fuels

The overall cost of current closed cycle (interim storage, recycling, transportation, waste disposal) is about 6% of the cost of producing electricity (Barbat and Liberge, 2013, pp. 70).

The cost covers transportation of used fuel from reactor storage, reprocessing of used fuel, treatment and disposal of HLW resulting from reprocessing, and construction-operation-decommissioning of the plant. It incorporates saving up to 25% of natural uranium equivalent. Due to the recycling of the spent fuel, the front-end costs for utilities are lower thanks to the recovering of uranium and plutonium. Recycled fuel credits offset up to 40% of recycling costs, which are now comparable to direct disposal costs (Barbat and Liberge, 2013, pp. 76). Recycling also reduces financial uncertainties in the back-end by relying on industrial facilities

Fig. 13 Comparison of fission gas release for MOX and UOX fuel.

with proven track records, recycling costs, as well as transportation costs. These costs are fully controlled. In closed fuel cycle, only waste disposal presents a certain level of financial uncertainty as no geological disposal for high-level waste (HLW) is already in operation worldwide.

However, in case of closed cycle these disposal costs are reduced compared to open cycle for several reasons:

- Due to volume reduction there is less waste to be disposed of,
- thermal power of recycling waste decreases much faster than thermal power of spent fuel,
- HLW from recycling can be put in interim storage with safe and durable conditions,
- the need for final disposal can be delayed and HLW is more compact than used fuel in the final disposal.

On the contrary, the majority of direct disposal costs (encapsulation and geological disposal) are unproven leading to large uncertainties associated with the spent fuel management route. Recycling is a competitive solution which reduces financial uncertainties compared to direct disposal, in Geological Disposal Facilities (GDF), in which actual costs will only be revealed in the future.

Mixed Oxide (MOX) and Enriched Reprocessed Uranium (ERU) are respectively competitive.

Cost associated to MOX fuels

The respective competitiveness of Mixed Oxide (MOX) and Enriched Reprocessed Uranium (ERU) will be explored further in the sub-chapter below.

MOX fuel costs are not affected by the volatility of the cost of natural uranium supply. MOX fuel represents a secured source of supplies with a very high stability and predictability rate. This is a unique feature for utilities. To support the general, long-term trend (higher fuel burnup) an increase of uranium consumption and enrichment is required in the case of UO_2 fuel leading to cost augmentation. In the case of MOX fuel, the increase of plutonium content is enough to sustain the rise of fuel burnup which has a small impact on the fuel cost. Currently, MOX fuel fabrication is more expensive than UO_2 fuel fabrication. This is partly due to the specific safety and radiation protection measures required in MOX fuel fabrication plants for the safe handling of plutonium. The main reasons for the high cost of MOX fuel fabrication are the small sizes of the facilities and the relatively early stage of development of the recycling industry.

Fig. 14 MOX microstructure in different pellet areas.

The overall cost of production numbers per unit are:

- \$400/kgU for UOX LWR
- \$1000/kgHM for MOX LWR

Reference costs from international sources based on reference capacity in dollars (\$) of the year, 2017 ([Advanced Fuel Cycle Cost Basis, 2017](#)).

Costs associated to RepU and ERU fuels

Reprocessed uranium can be used as a direct substitution in fuel fabrication. Reprocessed uranium's main advantage is the cost predictability due to the absence of price volatility in contrast to natural uranium prices. If natural uranium prices remain high and if suitable enrichment capacities are available, a policy of sustained single cycle of RepU could reduce primary uranium demand by 15% or more. It will also give NPPs a way to diversify their supplies.

For CANDU fuel, the use of RepU can provide a direct economical saving as demonstrated in the [Table 1](#).

For ERU fuel, as the isotopic composition brings more constraints, the overall cost of fuel manufacturing is higher than normal ENU fuel.

Fig. 15 Pu repartition illustrating heterogeneous structure.

Table 1 Price comparison using RepU.

<i>Economics of the Use of LWR Reprocessed U in CANDU Reactors</i>		
<i>Natural U CANDU fuel from uranium ore:</i>		
Uranium ore price (English)	89.6	\$/lb U308
Uranium mine & mill price (Metric) (as if U308 produced)	233	\$/kgU
Canadian conv of U-mill solutions to pure reactor-grade UO ₂	10	\$/kgU
CANDU fuel fabrication price (from UO ₂ powder)	100	\$/kgU
Total cost	343	\$/kgU
CANDU FUEL FROM LWR REPROCESSED U^a		
Dissolution of REPU308, cleanup of sol'n, and conversion to UO ₂ of right powder morphology	40	\$/kgU
CANDU fuel fab price (adj for higher handling risk)	130	\$/kgU
Total cost	170	\$/kgU

^aNo enrichment step assumed. ~ 0.7%–0.9% U-235 in REPU; some U-236 present.

The cost numbers coming from international sources: (Shropshire et al., 2006).

- \$400/kgU for UOX ENU LWR
- \$435/kgU for UOX ERU LWR

Reference costs based on capacity in dollars (\$) of the year, 2017 (Shropshire et al., 2006).

The current industrial mono-recycling of U and Pu

In conclusion, recycling of recycled uranium and plutonium in MOX fuel has demonstrated its competitiveness throughout the world for over 45 years. Recycling provides a long-term source of fuel supply, independently from uranium markets volatility. MOX fuel and RepU fuel are based on the simple principle that they must be equivalent to natural uranium fuels for power generated, overall reactivity and accumulated burnup. The MOX fuel have met all safety criteria in manufacturing, transport and reactor operation. From the financial point of view, recycling reduces uncertainties and is based on proven industrial technologies.

Goals of Pu multi-recycling

Plutonium formation and amount in used fuels

Plutonium in LWR enriched uranium classical fuel is formed in the reactor core by neutron capture reactions on ^{238}U , which is “not fissile” at low neutron energy (“thermal spectrum,” which prevails in light water reactors cores), but is able to be transformed into ^{239}U . This uranium isotope is unstable and, by β -successive decays, is spontaneously transformed (decay half-time: 23.5 min) into ^{239}Np then (decay half-time: 2.35 days) into ^{239}Pu .

The global mechanism is the following:

From ^{239}Pu many different events can then occur: either fission (^{239}Pu is fissile in thermal spectrum) or successive capture reactions, resulting in higher isotopes successive formation (^{240}Pu , ^{241}Pu , ^{242}Pu mainly). And each of them can then be transformed, either by fission (for the odd isotopes) or radioactive decay α decay with long radioactive periods, but also β -decay leading to trans-plutonian elements (Am, Cm mainly).

^{238}Pu can also be formed: either by capture reactions on ^{235}U and ^{236}U (leading to ^{237}U , then ^{237}Np which can evolve toward ^{238}Np the ^{238}Pu), or by spontaneous α decay from ^{241}Am , previously formed by mechanisms mentioned just above.

The main radioactive periods and absorption and fission cross-sections of uranium and plutonium isotopes are reminded in Table 1 and Fig. 1 hereafter.

The respective amount of plutonium isotopes in typical enriched uranium oxide used fuels are presented in the following Table 2.

It must be noticed that the plutonium amount in used fuel reaches an equilibrium value in the core of the LWR, due to antagonistic mechanisms: on the one hand, Pu is formed through capture on ^{238}U , and on the other hand, it is eliminated by fission, capture or decay. The global amount of plutonium in LWR used fuel is thus about 1% (mass fraction), almost not depending on the residence time of the fuel in the reactor core.

The duality of plutonium: Asset and hazards

- *Residual energy value:* Plutonium odd isotopes (^{239}Pu , ^{241}Pu) are fissile in thermal neutron spectra, and a large part of the formed Pu is fissioned before fuel unloading (about 30% of global recovered energy from the fuel is due to in situ formed plutonium). Plutonium in used fuel represents about 1% of the total mass of initial uranium, and more than half of the Pu isotopes are fissile/odd isotopes. This is why plutonium amount in used fuel can be considered as an asset, for fissile potential of it is about 20% of initial ^{235}U fissile potential.

Table 1 Radioactive decay half-life of uranium and plutonium isotopes.

Isotope	^{234}U	^{235}U	^{236}U	^{238}U	
$T_{1/2}$ (years)	2.454×10^5	7.037×10^8	2.342×10^7	4.468×10^9	
Isotope	^{238}Pu	^{239}Pu	^{240}Pu	^{241}Pu	^{242}Pu
$T_{1/2}$ (years)	87.71	24.1321×10^3	6.569×10^3	13.355	3.76×10^5

- *Plutonium potential radiotoxicity*: plutonium isotopes are heavy nuclei, which all belong to long decay chains with α -active radionuclides, a large part of them being long-lived. This leads plutonium isotopes to be the main source of long term radiotoxicity of used fuels: the plutonium share in the total radiotoxicity of used fuels is higher than 90% after one century after used fuel discharge from reactor (see Fig. 2).

Finally, plutonium is a source of proliferation concerns: any plutonium amount, in any material, used fuel or waste form, has to be strictly controlled to prevent any diversion.

Plutonium recycling incentives

According to plutonium properties and their potential consequences mentioned above, one can draw several incentives for plutonium recycling in nuclear reactors.

1. *To take advantage of plutonium energy value*: this could extend the use of initial uranium loaded in the reactor; if plutonium recovered in used fuel is re-loaded and fissioned, the part of initial ^{238}U which has been transformed into plutonium can be valorized. The efficiency of such a strategy depends on the efficiency of ^{238}U to ^{239}Pu conversion, and also of the ability of the diverse plutonium isotopes to be efficiently fissioned (for both aspects, fast neutron reactors appear far more efficient than thermal neutron reactors). In an idealistic case, if the conversion of ^{238}U is quantitative, all the initial uranium isotopes could be either directly (^{235}U) or indirectly (^{238}U) fissioned, and thus the energy yield of the fuel can be increased by about 100.
2. *To improve the final waste management*: indeed, by removing plutonium from the waste, recycling drastically decreases the long term "radiotoxic inventory." The gain is however limited by the amplitude of formation of minor actinides (from high plutonium isotopes β -decay), and depends on the nuclear reactor characteristics. As for fission, the highest performance is obtained with fast neutron reactors, which favors plutonium fission (vs. capture then decay) at the expense of minor actinides formation.
3. *The impact on proliferation issues is not to be determined in a general manner*: recycling plutonium leads to plutonium consumption (thus a favorable effect) but the recycling operation may use processes and technologies leading to potentially temporary increase in plutonium accessibility, needing a case per case in depth analysis to be conclusive and adapted safeguards regulations and technologies to prevent any diversion of material.

The physics of Pu recycling in nuclear reactors

Plutonium in thermal neutron spectrum: Potentialities and limitations

The average neutron flux in light water reactor is presented in Fig. 3 (Santamarina et al., 2009).

According to plutonium isotopes cross-sections presented in section "Plutonium formation and amount in used fuels," one can draw the following conclusions:

- (1) The high energy part of the flux, even if the most important, is of far lower importance on plutonium nuclei transformations than the low energy part: this is due to the respective values of absorption cross-sections in these two different zones, far higher for thermal neutrons than for fast neutrons.
- (2) Odd plutonium isotopes (^{239}Pu , ^{241}Pu) present rather high fission versus absorption ratio values in the thermal zone of the neutron flux; in this respect, their behavior is similar to ^{235}U behavior in a thermal reactor.
- (3) Even plutonium isotopes (^{238}Pu , ^{240}Pu , ^{242}Pu) present very low fission versus absorption ratio values in the thermal zone of the neutron flux; in this respect, their behavior can be seen as introducing a "poisoning" effect into the reactor core (that is, absorbing neutrons), that leads to the formation of higher plutonium isotopes (and then minor actinides by spontaneous β -radioactive decay).
- (4) Even plutonium isotopes (notably ^{240}Pu and even more ^{242}Pu) present high fission to absorption ratio value in the high-energy zone of neutron flux ("fast neutrons" zone). This has to be considered in assessing the thermal reactor core safety (effect on the reactivity of a loss of moderator resulting in spectrum hardening), and can limit the effective load of plutonium in light water reactors.

Plutonium in fast neutron spectrum: Potentialities and limitations

The average neutron flux in fast neutron reactor is presented in Fig. 4 (Rimpault et al., 2002).

Fig. 1 Fission and capture cross-sections of plutonium isotopes (^{238}Pu to ^{242}Pu , barns) versus incident neutron energy (eV). From JANIS data bank, JEFF3, Nuclear Energy Agency.

Table 2 Plutonium isotopes amount in used fuel^a.

^aEnriched natural uranium oxide fuel, initial enrichment 3.7%, average burn-up 46 GW days /t.

^bApproximatively: 2.8 t used fuels at 46 GWd/t needed to get 1 TWhe of electricity.

From French CEA COSI code calculations.

Fig. 2 Contribution of diverse components to the radiotoxicity of used fuel versus time after discharge. From: OECD/NEA (2006) *Physics and Safety of Transmutation Systems: A Status Report* (Report 6090).

According to plutonium isotopes cross-sections presented in section “**Plutonium formation and amount in used fuels**”, one can draw the following conclusions:

- (1) The most important feature is that fast neutron reactors don’t present any significant part of the flux in the thermal zone: Pu nuclei transformations occur in the high neutron energy zone, where absorption cross-sections are far lower than in thermal zone, but fission to absorption ratio values are higher.
- (2) Both odd and even plutonium isotopes present high fission to absorption ratio values: for all plutonium isotopes, the dominant processes is fission.

The average “secondary” neutrons resulting from fission (η = number of fission neutrons generated per neutron absorbed) is presented in **Fig. 5** (for diverse nuclei fission, and for diverse incident neutron energy range).

Typical values are given in **Table 3**, respectively for Light water reactors and fast neutron reactors.

It can be noticed that ²³⁹Pu fission at high neutron energy provides higher η values than ²³⁵U or ²³⁹Pu fission at low neutron energy. This provides in the first case more available neutrons, which can be used to convert ²³⁸U into ²³⁹Pu. Consequently, the conversion ratio of ²³⁸U is higher in a fast reactor than in a thermal neutron reactor because fast neutron reactor uses ²³⁹Pu as the main fissile isotope.

Plutonium recycling in light water reactors

Plutonium first recycling in LWR: The MOX option

Plutonium recycle is currently operated in France: Natural enriched uranium used fuel is reprocessed, and the totality of the recovered plutonium is reloaded in the nuclear fleet as Mixed OXide (MOX) fuel. MOX fuel is obtained by mixing recovered Pu (which is here the fissile element, replacing ^{235}U) with depleted uranium (essentially ^{238}U , ^{235}U content 0.1–0.3%). Plutonium content in the fuel depends on the isotopic ratio, and is about 5–10% in average: this provides a reactivity of the fuel analog to enriched uranium fuel (4% ^{235}U).

Fig. 5 η values vs neutron energy for diverse fissile nuclei (^{233}U , ^{235}U , ^{239}Pu). From: Wigeland R et al. (2014) *Nuclear Fuel Cycle Evaluation and Screening*, Final Report, I DOE-FCRD-2014/106.

Table 3 η average values in typical light water and fast neutron reactors.

	PWR spectrum	FR spectrum
U^{235}	2.0	1.9
Pu^{239}	1.8	2.3

From: BUSSAC and REUSS (n.d.) *Traité de neutronique*, Hermann ISBN.

The **Table 1** (see above) presents average isotopic content of plutonium recovered from enriched uranium used fuel; ^{239}Pu is the main isotope, but the higher is the burn-up of the fuel, the higher is the content of high plutonium isotopes (^{240}Pu and above) in recovered Pu, and the lower is its average reactivity in thermal spectrum. So, the higher burn-up is, the higher the global plutonium content must be in MOX fuel; and the trend to increase fuel burn-up in reactors in the previous decades (from about 30 GWd/t up to about 50 GWd/t) lead to increase Pu content in MOX fuels from about 6% to almost 10% currently.

MOX fuel form consists in mixed oxide ($\text{UO}_2\text{-PuO}_2$) homogeneous pellets, put into rods sub-assemblies strictly identical to enriched uranium ones; if recovered plutonium is complete, MOX fuel is about 10% of the total fuel in the fleet. The presence of MOX subassemblies in the core leads to some changes: as this can be seen on **Fig. 6**, and by comparing to **Fig. 3**, neutron spectrum is slightly “hardened” by plutonium enhanced thermal neutrons absorption, with consequences on reactor control rods behavior, needing some adjustments.

In the French fleet, MOX assemblies are combined with enriched uranium assemblies up to 30% in some dedicated reactors being MOX assemblies. **Fig. 7** presents the principle of the current French recycling policy: used enriched uranium fuels are systematically reprocessed, recovered plutonium is recycled as MOX fuels (in addition to plutonium systematical recycling, recovered uranium in used fuels can be re-enriched and reloaded too), used MOX fuels are not reprocessed and are currently stored in pools.

MOX fuels are currently not reprocessed not because of a technical impossibility (the specificities and difficulties can be overcome; industrial demonstrative campaigns have demonstrated the feasibility of such an operation on more than 70 t), but because the isotopic content of plutonium recovered from used MOX fuels is not suitable for an efficient use in LWRs (see **Table 4**).

Fig. 6 Neutron flux typical distribution vs neutron energy in a light water reactor fuel with UOX (red) fueled with one third MOX (orange) and for sodium fast neutron reactors (blue). From CEA.

The values presented in Table 4 show significantly lower fraction of odd (fissile) Pu isotopes in the used MOX fuel that effects Pu recycle in thermal reactors:

- The higher relative amounts of ^{240}Pu and ^{242}Pu require an increase of plutonium concentration in MOX fuels to recover the targeted nominal reactivity, but this is limited by safety concerns due to even isotopes neutronic behavior in some incidental conditions (cf. section "Plutonium in thermal neutron spectrum: Potentialities and limitations" (4)).

An additional recycle is possible by combining Pu with different isotopic compositions, but an infinitely recurrent recycling of plutonium in standard (current) MOX form is thus practically not possible in LWRs.

Fig. 7 The current nuclear fuel cycle in France (annual amount). From: CEA (2012) *Sustainable Radioactive Waste Management*, Report to French Government, 2006 Act.

Table 4 Plutonium isotopic content in uranium oxide fuels and in MOX fuels.

Pu isotope	Pu from used UOX	Pu from used MOX
^{238}Pu	2.3%	3.5%
^{239}Pu	51.4%	38.6%
^{240}Pu	24.2%	29.9%
^{241}Pu	15.0%	16.5%
^{242}Pu	7.1%	11.5%

Advanced potential recycling concepts

In order to tackle this impossibility to indefinite recycling, two main ideas could be thought about to reach a recurrent recycle of plutonium in LWRs:

- (1) Isotopic separation of even plutonium isotopes, to maintain the “isotopic quality” of recycled plutonium all along the “multi-recycling” process by purging it from its non-fissile isotopes. This seems theoretically possible, but with (i) the technical difficulty related to isotopic separation operation, (ii) the necessity of confining in long lasting wastefoms the non-recycled (rejected) plutonium isotopes, and (iii) high security concerns about the potential increased proliferation risks. This route has never been considered by any country for industrial operation, and does not seem to be considered by any important research effort.
- (2) Add enriched uranium to recovered plutonium to compensate the decrease in fissile plutonium isotopes: this is the basis of several concepts under development today (especially in Russia and in France).
 - First, enriched uranium oxide (^{235}U about 1% or 2%) can be blended with plutonium oxide to increase the reactivity of the mixture, and thus allow an efficient behavior in the reactor within comfortable safety margins. In such conditions, plutonium total content in the fuel remains about 10%, as in current MOX fuel: the difference is that uranium is enriched a little, instead of depleted uranium in standard MOX fuel. This route is referred to as the homogeneous plutonium recycling.
 - Second, a heterogeneous route can also be developed by mixing in a same fuel sub assembly both standard MOX rods (about 10% plutonium and depleted uranium, with a lack of reactivity if plutonium presents large amount of heavy isotopes), and enriched uranium rods (^{235}U content higher than standard value to compensate the presence of the “under reactive” MOX rods).

Both concepts have been under research: for instance, MIX (homogeneous) or CORAIL (heterogeneous) designs have been studied by French teams, and pilot-scale experimentations are scheduled for the coming decade.

Table 5 Estimate of the effects of (hypothetic) CORAIL and MIX implementation in the French fleet (vs. open fuel cycle and current mono-recycle options) considering a French nuclear fleet of 63.2 GWe LWR providing 400 TWh_e per year.

	<i>U and Pu mono-recycle</i>	<i>CORAIL multi-recycle</i>	<i>MIX 9.54% multi-recycle</i>	<i>Fast reactor multi-recycle</i>	<i>Open cycle</i>
Fraction of MIX/CORAIL or FRs in the fleet	0%	87%	35%	100%	0
U _{nat} consumption (t/year)	6000	6300	5500	0	7500
Pu inventory (t/year)	+ 7.2	Stabilized	Stabilized	Stabilized	+ 9.9
Minor actinide inventory (t/year)	+ 3.3	+ 4.2	+ 4.5	+ 2.3	+ 2.7
Increase in spent fuel inventory (t/y)	180	0	0	0	950

From: Chabert C (2019) *Prospective Inventory of Radioactive Materials and Waste Produced by the French Nuclear Fleet According to Various Options*. Global 2019, Seattle.

The impact of these specific designs on LWRs fleets has also been assessed (see Table 5 for the French case): it can be seen that this could effectively allow plutonium multi-recycling and thus avoid used fuel plutonium accumulation. The main drawbacks are, besides complication of fuel cycle operations, the formation of higher amount of minor actinides (americium and curium) by increased capture reactions on plutonium nuclides followed by β^- radioactive decay. In Table 5 are presented the main results of the implementation of plutonium recycling devices (CORAIL or MIX) in the current french fleet (from Chabert, 2019).

Plutonium recycling in fast neutron reactors

Plutonium physics in fast reactors presents principle advantages, due to more favorable physical properties, and notably (cf. section “Plutonium in fast neutron spectrum: Potentialities and limitations”):

- fission to capture cross-sections ratio higher than in thermal reactors;
- easier conversion of ^{238}U to ^{239}Pu , thanks to η values higher than in thermal reactors (cf. section “Plutonium in fast neutron spectrum: Potentialities and limitations”).

These advantages can open the way to several nuclear systems for several diverse purposes.

Self-sustainable nuclear systems

Based upon the two main advantages recalled just above, one can imagine a recurrent plutonium and uranium systematical recycle in fast neutron reactors (see Fig. 8).

In such schemes, the fissile element is plutonium, initially loaded in the core and then continuously produced from neutron capture in the non-fissile ^{238}U . Plutonium can be multi-recycled without any limitation, as all plutonium isotopes (both odd and even isotopes) are fissile in fast neutron flux. This is the consequence of the two main advantages of fast neutron spectra described in the first paragraph.

So, the fuel can be a mixture of plutonium and depleted uranium (both metallic and oxide forms have been experimented worldwide). Inside the core, a part of the plutonium is fissioned (resulting in energy release and in FPs formation), and a part of uranium is converted into plutonium (^{239}Pu). Discharged used fuel is reprocessed, fission products (and also the amount of minor actinides formed by capture reactions in Pu isotopes and their capture reaction products) are removed, and recovered uranium and plutonium are recycled and refueled in a recurrent way, without any physics-based limitation. A complement of

Fig. 8 The principle of U Pu multirecycle in a fleet of fast neutron reactors.

^{238}U (depleted or natural uranium) is added to the reloaded fuel in order to compensate for the amount used primarily by neutron capture (making Pu) by fissions induced by fast neutrons (thus making the neutron economy in fast reactors even better).

Fast reactor cores can be designed in several ways:

- (1) *Plutonium consumption is perfectly balanced by plutonium formation*: the system is “self-balanced,” and can last as long as ^{238}U uranium is available. Considering the fact that ^{238}U amount is rather abundant in earth crust, more than 100 times higher than ^{235}U amount (and also that depleted uranium stockpiles are currently very large worldwide), one can speak of self-sustainable nuclear systems (able for instance for France, to provide electricity for more than 1000 years, with today estimated uranium reserves and current electricity consumption).
- (2) *Plutonium formation is higher than plutonium consumption*: the system is a breeder (overproduction of plutonium): this can allow expansion of the nuclear power plants fleet, by making initial fuel loading for new reactors using the plutonium excess recovered from used fuels.
- (3) *Plutonium formation is lower than plutonium conversion*: the system is not able to be operated in a sustainable way without adding fissile nuclides (i.e., plutonium) regularly to the recycled fuel. This option is not as interesting as the two other ones, except for plutonium inventory reduction purposes as explained hereafter in section “**Plutonium burners**”.

Plutonium burners

Here the purpose is *not* to deploy sustainable nuclear systems based on ^{238}U conversion to produce plutonium; the purpose is to decrease plutonium amount (either separated available plutonium, or plutonium content in used fuel stockpiles). Fast neutron reactors can be used, as plutonium can be efficiently consumed (by fissions, providing energy), without any limitation on number of recycling. The main “principle” issue in this case is that if uranium is also present in the fuel, it will be partly converted into plutonium again, which compensates plutonium consumption.

So, to reach high plutonium consumption rates, it seems natural to think in this case about uranium-free fuels: here one would get pure plutonium burners, but some important difficulties have to be overcome. ^{238}U presence in the core is key for reactor safety, notably thanks to significant “Doppler effect” provided to decrease core reactivity upon fuel temperature increase in incidental conditions. ^{238}U conversion is also useful to maintain the reactivity of the core all along reactor operation with the fuel (in situ formed plutonium compensates plutonium amount decrease due to fissions and neutron captures). These are real issues or concerns, and actually, attempts for designing plutonium consumption fast neutron cores have up to now essentially tried to limit uranium amount in the fuel, not to get rid of it.

One example is the “CAPRA” project in France: in the specific case of a nuclear fleet phase-out decision, the future fast reactors fleet could directly be used to burn plutonium thanks to a significant modification of the fuel. In order to effectively consume plutonium, the CAPRA principle is to increase the plutonium content and decrease the uranium content in the fuel. In an hypothetical fast reactor fleet with plutonium content in the fuel up to 40% (which could lead to some issues regarding diverse items, not considered at this step), the global plutonium inventory within the fleet could be decreased by about 30% in 30 years (CEA, 2012).

Synergic systems (using both LWR and fast neutron reactors)

Self-sustainable fast reactors fleet appears in some respects promising, but could remain (it’s a possibility) more sophisticated, more expensive than LWR fleet. On the other hand, LWR present important advantages, but can’t meet alone long-term sustainability goals. So, symbiotic fleets have been thought to, incorporating fast reactors to improve uranium and plutonium management, but keeping a strong basis of LWRs. This could also be seen as a pathway to evolve from a LWR fleet to future fast reactor fleet, in a progressive stepwise approach.

Plutonium multi-recycling in such schemes is possible, and a comprehensive study has been performed to assess several routes for the evolution of the current French LWR fleet. Table 6 presents, for diverse FR/LWR ratio in the fleet, the values of some key-variables (from CEA, 2015). The main conclusions are that the higher fast reactors in the fleet, the higher plutonium recycling potentialities, and thus the lower natural uranium consumption and the lower used fuels stockpiles.

Table 6 Effect of an increased fraction of FR in a LWR fleet on key fuel cycle attributes.

	Open cycle (0)	UPu monorecycle	UPu multirecycle
Fraction of FRs in the fleet	0	0%	31%
U_{nat} consumption (t/year)	7500	6000	3400
Pu inventory (t/year)	↗ 9.9	↗ 7.2	Stabilized
Minor actinide inventory (t/year)	↗ 2.7	↗ 3.3	↗ 4.4
Unrecycled used spent fuel to be stored (t/year)	950	180	0

The minor actinides issue

Minor actinides in used fuels

Capture nuclear reactions in nuclear reactors lead to formation of transuranic elements: plutonium is the most abundant in spent fuel, but significant build-up (about 0.1–0.5% total mass) of neptunium and of “trans-plutonium” elements are also observed, in particular for high burn-up fuels.

- Neptunium (long-lived ^{237}Np is the only noticeable isotope, as others are short-lived) can be formed either by successive capture reactions in ^{235}U , or by (n,2n) reactions in ^{238}U , followed by β -decay; it can also be formed more indirectly by alpha decay from heavier transplutonic isotopes.
- Americium (mainly ^{241}Am and ^{243}Am , as other isotopes are short-lived) is formed by capture reactions followed by β -decay from plutonium isotopes (^{240}Pu and ^{242}Pu respectively for ^{241}Am and ^{243}Am).
- Curium (mainly ^{244}Cm , ^{245}Cm) are resulting from capture reactions in americium isotopes followed by β -decay; ^{242}Cm is also formed (from ^{241}Am), but is converted relatively quickly (its half-life is $\sim 1/2$ year by alpha-decay into ^{238}Pu).
- Heavier elements (Cf, Bk) are also produced during fuel residence in the nuclear reactor, but their respective quantities are very low (producing, by β -decay, Cf isotopes from Cm, needs several successive neutron captures from ^{244}Cm up to ^{248}Cm , which is of low occurrence).

Table 7 presents the respective amount (Kg/TWhe) of these elements in used fuels.

The following main observations can be noticed:

- (1) The total build-up of other than plutonium transuranic elements is about few ‰, of the total used fuel mass, that is to say about one tenth of plutonium build-up. That is why Np, Am and Cm are called “minor” actinides, as their respective amount in used fuel is rather low.
- (2) All minor actinide isotopes are heavy nuclides, far from stability state and each of them belongs to a long alpha decay chain (with alternate alpha and β -emitters before reaching stable nuclides). All of them are, directly or by their decay products, source of long-lasting alpha radioactivity (in all chains, presence of at least one long-lived alpha active nuclide).
- (3) The higher the fuel burn-up, the higher the minor actinide content (no significant consumption by fission, fission average cross-sections are rather low for the mentioned minor actinide isotopes).
- (4) For plutonium-based fuels (MOX fuels), Am and Cm amounts are higher than for enriched uranium fuels (due to formation mechanisms exposed just above); it's the contrary for neptunium, for a large part coming from ^{235}U neutron capture.
- (5) In fast neutron reactors fuel, minor actinide amounts are lower than in thermal reactors fuel: this is due to plutonium isotopes fission to capture cross-sections ratio (higher for fast neutrons and leading to plutonium fission rather than forming higher plutonium isotopes, potential minor actinide source).

The goals of minor actinide recycling

minor actinides (MA) amounts in used fuels are, because of their radioactive properties (long-lived alpha emitters), the second contributor to long term used fuel radiotoxicity¹ (the very first one is plutonium, 10 times higher due to higher amount). Recycling

Table 7 Minor actinide amount (in kg/TWhe) in used fuels (i) at fuel discharge; (ii) 5 years after fuel discharge.

(i)	Typical enriched uranium fuel (LWR) 46 GWd/t	Typical MOX fuel (LWR) 46 GWd/t	Typical FR MOX fuel 81 GWd/t
Np	1.7	0.4	0.4
Am	0.7	5.0	1.7
Cm	0.3	4.1	0.3
MA ^a	2.7	9.5	2.4
(ii)	Typical enriched uranium fuel (LWR) 46 GWd/t	Typical MOX fuel (LWR) 46 GWd/t	Typical FR MOX fuel 81 GWd/t
Np	1.7	0.4	0.3
Am	1.7	10.9	3.1
Cm	0.2	2.9	0.1
MA ^a	3.6	14.2	3.5

^aTotal MA, total minor actinide content.
From French COSI code calculations.

¹Radiotoxicity: dose (Sv) delivered per unit of intake (Bq)

minor actinides, *in addition to prior plutonium recycle*, can offer a significant reduction of final waste long term radiotoxicity (after three centuries, MA contribution to global radiotoxicity is several orders of magnitude higher than residual fission products contribution). This has been a strong incentive for research in the field of MA separation and recycling; but the following should be noticed:

- (1) Converting a minor actinide nuclide into another minor actinide nuclide (by neutron capture) is inefficient if the goal is to decrease long term radiotoxicity of the final waste; as mentioned in section “**Minor actinides in used fuels**” (2) all of them can be considered as long-lived alpha emitters, with a comparable radiotoxicity. To decrease radiotoxicity, only fission is efficient (to get shorter-lived fission products).
- (2) MA recycling can make sense only if plutonium has been first removed from final waste; it's clearly a “secondary” issue.
- (3) The benefit of MA recycling is still a matter of debate: intrinsic radiotoxicity of final waste must be balanced by the confinement properties of the final repository. For instance, MA are almost not mobile in the deep clay-rich layers as those considered in France for the repository. The long-term impact of the repository is therefore driven by some more soluble and mobile fission products although they are less radiotoxic. In such a case the direct advantage of MA recycling is therefore questionable, and “cost to benefit” approaches has been launched in order to assess (in respect to several diverse attributes and criteria) the relevance of minor actinide recycle.

Another incentive often mentioned is the residual *heat load of final waste*, which is a key parameter for designing the deep repository, with direct influence on the overall cost. After about one century, spent fuel residual heat load is mainly due to ^{241}Am radioactivity (^{241}Am is the only present nuclide with half time of about several centuries). This could be a real incentive for Am recycle, in particular in the case of final deep repository, whose compactness is governed by decay heat emission.

Minor actinide recycling in fast neutron reactors

According to section “**The goals of minor actinide recycling**” (1), minor actinides have to be recycled into reactors able to provide their fission. Fission to absorption cross-section ratios for the minor actinide nuclides of interest (^{237}Np , ^{241}Am , ^{243}Am , ^{244}Am) are very low in thermal spectrum: water-cooled reactors are not suitable to get a significant amount of MA fission, and it would be no use to recycle them into such reactors. It would lead to the production of higher isotopes, without any significant decrease in radiotoxicity.

Fast reactors have therefore to be considered for this purpose: fission to absorption ratio is more favorable (although not so high, far lower than for plutonium isotopes, except for neptunium). Fission routes are more complicated than plutonium ones, not direct but often consisting successive capture reactions, radioactive decay and finally fission (see for instance the ^{241}Am transmutation case). Complete transformation of fed MA requires longer residence times and could hardly been reached without MA multi-recycling (that is to say MA-bearing targets loading into the reactor, processing of unloaded MA-bearing targets for residual MA recovery and reload, and so on...). Experiments have been achieved with “once through” irradiation of MA-bearing targets: about less than 50% of MA initial content have been fissioned in average, which appears far from enough; it seems it would be difficult to reach high fission yields using once through targets, without significant (and unacceptable) neutron induced radiation damage (notably important swelling).

So, diverse routes have been considered for MA multi-recycling in fast reactors:

- (1) *Homogeneous MA recycling*: MA are diluted in the whole core fuel, processed and recycled with plutonium and uranium.
- (2) *Heterogeneous MA recycling*: MA are concentrated in specific targets (MA bearing core fuels or dedicated MA bearing blankets); processing and recycling requires dedicated facilities.
- (3) *Dedicated strata*: MA are recycled in specific fast reactors, dedicated to MA transmutation (the “dedicated strata,” while the main strata is for power generation). A particular option for this route is the “accelerator driven systems” (ADS), with a sub-critical core and extra-neutrons provided to the system (for instance by spallation reactions) (Abderrahim and De Bruyn, 2021).

Each route (which have not yet been studied at higher scale than laboratory-scale) would present advantages and drawbacks (see Wigeland et al., 2014) in brief:

- The homogeneous recycling route presents the disadvantage of “contaminating” the whole fuel of the nuclear fleet, and also leads to some safety issues due to MA unfavorable physical properties;
- The heterogeneous recycling route presents the advantage of “confining” MA to a tiny part of the fleet; but handling high MA concentration in dedicated fuels can be a difficult issue, and if blankets are placed at the periphery of the core, lower transmutation yields will result due to lower neutron flux;
- The dedicated strata with ADS devices still poses diverse physical and technological challenges, concerning both the control of the spallation reaction and the sub-critical core control with high minor actinide loading.

Additional information on multi-recycling in nuclear reactors can be found in Shwageraus (2021), Wigeland and Taiwo (2021) and Krepel (2021).

Introduction

Plutonium multi-recycling is the term applied to nuclear fuel cycles in which spent fuels from reactors are reprocessed to recover uranium and plutonium which are then fabricated into new fuel for re-use in the reactor. Unlike the twice through cycle (TTC), in which the plutonium is only recycled once and the spent mixed oxide (MOX) fuels are then stored ready for disposal, in this scenario the spent MOX fuels are reprocessed and the plutonium re-used in new fuels multiple times. The TTC has been industrially implemented at commercial scales but, while it can be achieved in light water reactors (LWR), plutonium multi-recycling in fast neutron reactors (FR) is considered to be the optimum way to reach a fully closed and sustainable nuclear fuel cycle (see Chapter 7, [Boullis and Chabert, 2021](#)). The usual approach consists first in the reprocessing of spent LWR MOX fuels to recover Pu and produce FR MOX fuels to feed the first “Gen. IV” fast reactors deployed into the fleet. Then, in a second step, used FR MOX fuels are treated to recycle U and Pu and produce new FR fuels. Unlike Pu recycling in LWR fuels, the Pu isotopic composition in fast neutron spectra is not an issue and theoretically allows infinite recycling with no further need of using natural uranium resources.

However, as with the development of fast neutron reactors themselves, scientific and technological challenges have to be addressed to adapt the back-end of the nuclear fuel cycle and the associated facilities to meet this strategy. Indeed, current generation reprocessing plants are designed to reprocess spent uranium oxide or UOX-type fuels that contain approximately 1% plutonium once unloaded from pressurized or boiling water reactors (PWR or BWR). So while there is a substantial degree of feed-back already available from the industrial scale reprocessing of LWR fuels, for the reprocessing of FR MOX fuels industrial experience has been limited to specific campaigns or only performed through pilot units ([Masson et al., 2013](#)).

This chapter will, therefore, summarize some of the international experiences in reprocessing FR MOX fuels using the PUREX process and then describe some innovative approaches that aim to address the limitations of the PUREX process.

MOX reprocessing past experience and limitations of the existing PUREX process

In this section, firstly some past international experiences in reprocessing MOX fuels will be highlighted, particularly those undertaken at industrial or semi-industrial scales, and then some of the lessons that can be learned from these experiences will be summarized.

International experience

In France significant experience has been gained in the reprocessing of MOX fuels as part of the efforts to develop advanced fuel cycles based on plutonium multi-recycling. Indeed, 12 tons of used LWR MOX fuels were first reprocessed between 1991 and 1998 at the Marcoule pilot plant (APM) and the Orano La Hague UP2-400 plant. 63 tons were then treated at UP2-800 through four specific campaigns performed between 2004 and 2008 in order to confirm the feasibility of LWR MOX fuel reprocessing at an industrial scale. A large and unique pre-industrial experience is also available in France on the reprocessing of fast reactor fuels. Approximately 25 tons of FR MOX fuels unloaded from several sodium cooled fast reactors (SFR), including Rapsodie, Phenix (in France) and KNK (in Germany) were treated from 1969 to 1997 firstly at the AT1 workshop at la Hague and then at the Marcoule pilot plant (APM). These campaigns were performed either at a low rate (less than 5 t/y) or in dilution with larger quantities of used UOX fuels to mitigate the impact of MOX fuels on the process performance. Furthermore, up to 25 t of FR MOX were processed at the Marcoule Pilot plant at 1.5 kg of (U + Pu)/h without prior dilution of the MOX fuel liquor. While significant experience has been obtained over this period to demonstrate MOX reprocessing, the results also emphasize the limitations of the PUREX process to reach industrial treatment capacities with these specific fuels. Due to the characteristics of FR MOX assemblies and the higher content of Pu (see [Fig. 1](#)), the limitations were mainly related to the head-end steps; that is the mechanical dismantling and fuel dissolution steps. In fact, the dismantling of used FR MOX fuels was not carried out in the reprocessing plant but close to the reactor in the post-irradiation examination (PIE) cell and this operation was consequently identified to be the main issue for the development of future high-capacity industrial treatment.

The UK fast reactor program at Dounreay included a dedicated plant for the reprocessing of the spent fuels from both DFR (Dounreay Fast Reactor) and PFR (Prototype Fast Reactor) ([Judd and Ainsworth, 1998](#); [Natarajan, 2015](#)). The plant was designed to reprocess 120 day cooled MOX fuel with Pu contents of 17–25% and decay heat 3 kW per subassembly. 5.5 t of MOX fuels from PFR were reprocessed between 1980 and 1996 with burn ups of over 80 GWd/t and cooling times as low as 136 days. The plant used a PUREX based solvent extraction process with 3 cycles but using sulfate ions for plutonium separation. This is a separation based on the preferential complexation of Pu(IV) compared to U(VI) by the aqueous phase sulfate ions rather than the usual reductive stripping (using U(IV) and hydrazine, ferrous sulfamate or hydroxylamine). However, the use of sulfate ions is unattractive for future plants since it adds to the aqueous wastes, causes problems in vitrification and is potentially corrosive.

India has a detailed national program to develop nuclear energy including fast reactors as part of its 3-stage strategy ([Banerjee and Gupta, 2017](#)). Fuels from the Fast Breeder Test Reactor (FBTR) of up to 70% Pu content were reprocessed in the pilot scale CORAL facility with a peak burn up of 155 GWd/t and 2 year cooling period. However, the FBTR fuels were (U,Pu) carbide rather than oxide. The 500 MWe Prototype Fast Breeder Reactor (PFBR) being commissioned will use MOX fuel although subsequent units are planned with metallic fuels. The solvent extraction process was adapted to manage the high Pu content and the higher

Fig. 1 Main differences between LWR UOX, LWR MOX and FR MOX fuel compositions.

concentrations of fission products compared to the reprocessing of thermal fuels. Centrifugal contactors were installed for reprocessing FR fuels in order to manage the radiation dose to the solvent (Natarajan, 2015, 2017).

A number of tests have been made in the reprocessing of MOX fuel from Japan's JOYO reactor but these are mainly small scale using the Chemical Processing Facility (at JAEA's Tokai site). Some examples are described below in Section "Application of crySTALLIZATION for uranium separation" as part of the development of their NEXT process for FR fuel reprocessing. Kilogram quantities of MOX fuels from the KNK-II fast breeder reactor in Germany were processed in the pilot scale MILLI facility. These fuels had a maximum burn up of 100 GWd/t with 10 month cooling periods (Marth and Koehler, 1998; Natarajan, 2015).

Russia has also a large experience in MOX fuel fabrication and reprocessing. Recently, 8 fuel assemblies unloaded from the BN-600 reactor and with a burn-up of 73–89 and a cooling time from 17 to 21 years have been reprocessed in 2012 and 2014 at the RT-1 plant (Kolupaev et al., 2016). Uranium and plutonium were fully recovered and no increased losses of plutonium were detected compared to VVER-440 fuel reprocessing.

Lessons learned

As noted above, French experience clearly highlighted the challenges in the head end steps that must be addressed in preparing the spent FR MOX fuels for reprocessing. On the other hand, the increase of Pu content from 1% to 5% (in LWR MOX) and up to 30% (in FR MOX) in the spent fuels will impact the efficiency of the Pu recovery at the dissolution step. This is because a fraction of Pu is present as rich PuO_2 fragments in the fuel (that are more refractory to dissolution in refluxing nitric acid). Hence, dissolution under classical PUREX conditions would lead to an increase of residues and potential losses of Pu in the vitrified wastes. Such Pu losses can also be a criticality hazard if they were allowed to build up in the plant (Senentz, 2021).

The reprocessing of several tons of LWR and FR MOX in industrial or pilot scale reprocessing plants was a great opportunity to demonstrate reprocessing of Pu-rich fuels by hydrometallurgy. Nevertheless, it also highlighted the limitations to overcome to reach the industrial reprocessing capacity required for Pu multi-recycling in the future. Even if the main difficulties were focused on the head-end steps, it was clear that plutonium separation and purification from spent MOX fuels, fresh MOX fuel fabrication and wastes conditioning processes will also have to be adapted to take into account the higher content of Pu and the characteristics of spent MOX fuels. Moreover, in addition to the capacity to process high Pu content fuels, these new processes will have to:

- be more efficient (simple and compact) in order to be economically viable;
- be reliable and available (keeping in mind that in a closed fuel cycle the recycled products will be the unique source for feeding the reactors);
- be flexible enough to process LWR and FR MOX fuels as well as UOX fuels during the transition periods where both LWR and FR reactors will be present in the fleet;
- have enhanced global safety especially toward proliferation resistance;
- reduce the generation of wastes and more generally the environmental footprint in order to meet future regulatory and environmental requirements.

Over the last two decades, ambitious R&D programs have thus been launched in France, India, Japan and elsewhere to meet these challenges. While the exact approaches may differ, such R&D programs need to address the fundamental limitations and develop key processes for Pu multi-recycling including (Miguirditchian et al., 2017):

- an industrially scalable head-end process for MOX dissolution and full Pu recovery in solution;
- a new and simplified solvent extraction process for plutonium and uranium separation from Pu-rich solutions;
- a high-capacity process for plutonium and uranium co-conversion into mixed oxide and an automated and flexible MOX fabrication process avoiding powder milling and dust dissemination as far as practicable;
- an optimized management of the effluents and specific wastes generated by spent FR fuels.

The next sections will describe some proposed innovations developed internationally that aim to address these specific challenges.

Adaptation of the headend processes to FR fuel characteristics

The FR fuel assembly (here in the case of SFR fuel) is very different from an LWR fuel (see Fig. 1). In addition to the different cladding material (stainless steel vs zircaloy), the presence of a hexagonal wrapper tube and spacer wires around each pin makes the mechanical dismantling much more complex compared to LWR fuels. For instance, in France, dismantling was first performed at the Marcoule pilot plant by opening the wrapper tube (by mechanical drilling), removing the spacer wires and shifting the pins. Once separated, the pins were sheared mechanically. The number of operations and their complexity explains the difficulty with such approaches to increase the capacity treatment of FR fuels and reach industrially-relevant throughputs.

In the short term, a new industrial unit called TCP (for specific fuel treatment), dedicated to the shearing and dissolution of Pu-rich fuels (irradiated or not), is under development and should be implemented at the Orano UP2-800 La Hague plant (Durand et al., 2015). This unit, which is designed to treat up to 40 t/y of MOX fuels, includes a new shearing step, a dissolution unit and complementary steps to recover the residual plutonium still contained in the fuel cladding after rinsing and in the fine undissolved particles collected after feed clarification (see Fig. 2). The residual presence of undissolved particles is explained on one hand by the higher content of platinum group metal (PGM) elements in MOX fuels which form insoluble intermetallic phases in the presence of Pu. This behavior is particularly enhanced in the case of FR fuels because of higher burn-ups and higher temperatures in the pellets. On the other hand, refractory Pu-rich fragments can also be formed locally in the (U,Pu)O₂ oxide and will contribute to the increase of solid residues after MOX dissolution. R&D studies have recently shown that the quantity of residues is directly linked to the fabrication process and to the initial Pu enrichment (Bertrand et al., 2019).

To ensure quantitative Pu recovery and minimize the loss of Pu in the waste, an additional digestion step must be coupled to the primary dissolution. The digestion process is based on the principle of oxidizing dissolution with generated Ag(II). The process is currently being optimized at the laboratory scale in order to extend its use to a wide range of particles potentially containing Pu (Fig. 3). Similar studies focused around the oxidative dissolution process using Ag(II) are ongoing in the UK and elsewhere (Carrott et al., 2012; Natarajan, 2017). Ag(II) can be regenerated during the process and thus acts as a catalyst in the dissolution process; electrochemical generation or ozonolysis are leading technologies for Ag(II) generation. For comparison, an alternative complexing dissolution with HNO₃/HF was used in Russia for BN-600 irradiated fuel reprocessing (Kolupaev et al., 2016). The fuel was first dissolved in 10 M nitric acid and one or two complementary dissolution steps have been carried out with 1 g/L fluoride ions in HNO₃ to complete Pu dissolution.

In the longer term, new dismantling and dissolution processes should be proposed to ease the access to the fuel and reduce the overall size of the head-end steps (Fig. 4). Innovative shearing techniques avoiding the use of a mechanical blade such as a laser or water-jet are under assessment on mock-up assemblies at CEA. The goal is to reach a full separation of the irradiated oxide from the cladding in order to reduce the size of the dissolver and avoid the partial dissolution of the cladding in nitric acid. Complementary steps such as thermal treatment (voloxidation) might be used to help the oxide/cladding separation by a volume expansion of the fuel due to the phase transformation of the monolithic fluoritic UO₂ to orthorhombic α -U₃O₈ powder (Collins, 2018; Maher,

Fig. 2 3D view of Orano's new shearing and dissolution facility (TCP) currently at the project stage and simplified scheme of the TCP process.

Fig. 4 New head-end operations considered for used FR MOX fuel treatment.

2015). Once separated from the cladding, U-Pu-FP-MA powder will be dissolved in nitric acid in a very compact dissolver unit. A gain up to a factor of 10 is expected on the size of the dissolver compared to the wheel dissolver implemented in current industrial reprocessing plants (Netter, 2012).

Adaptation of the partitioning processes to the specificity of Pu from FNR fuels

While international experiences have demonstrated the application of the PUREX process to FR MOX fuel reprocessing, further process improvements are possible to adapt the separation flowsheet to higher Pu/U ratios. First, as illustrated in Fig. 5, several extraction and purification cycles were required to separate and purify U and Pu when applying historic PUREX reprocessing to FR fuels. Unlike the current PUREX process, a co-decontamination of U and Pu from FP and MA was performed in the first extraction cycle while Pu and U separation occurred in a 2nd extraction cycle. Each element was then submitted to a 3rd purification cycle to meet the purity standards. Into the future, the reduction of the number of cycles should, however, be possible and will improve the process compactness in order to reduce the cost of a future plant.

The main principle of the PUREX process, using tributyl phosphate (TBP) as the extracting ligand, is the exploitation of Pu redox chemistry. Pu/U partitioning is performed in the PUREX process by selective reduction of Pu(IV) to Pu(III) using U(IV) and hydrazinium nitrate ($N_2H_5^+$). If the use of these reducing agents is well managed at the industrial scale with UOX fuels, the increase of Pu content in LWR and FR MOX fuels will drastically increase the consumption of these reagents (up to a 10-fold increase of hydrazine,

Fig. 5 Toward an innovating separation process of U and Pu; above: the TBP process applied in the past to Phenix FR MOX dissolution liquor, below: the process under development (“one single cycle redox free”).

a hazardous and toxic chemical that presents specific safety issues in the process that must be managed). Furthermore, the increase of the Pu/U ratio in MOX fuel solutions makes the PUREX flowsheet more sensitive to critical parameters reducing the safety operating margins in case of process upsets such as changes in flowrates or critical reagent concentrations (TBP, U(IV), hydrazinium nitrate, etc.).

It is also important to notice that FR MOX fuels are generally irradiated to a very high burn-up and also may be short cooled. The combination of the higher Pu content (α , n radiolysis) and the higher FP content (β - γ radiolysis) will lead to a faster degradation of the organic solvent under radiolysis. Recommendations were made after these industrial campaigns to improve the solvent regeneration (solvent clean-up step) to keep high purification performances toward U and Pu purification or to substitute the extracting molecule to avoid any accumulations of troublesome degradation products (such as HDBP or MBP).

The development of a new 1 cycle extraction process that is redox-free for the separation of U and Pu has thus become a priority objective for the treatment of future spent MOX fuels. Three strategies are described below to illustrate this concept.

Use of a novel extracting ligand

The first strategy requires alternative extracting systems (not based on TBP) allowing U/Pu separation without needing redox control of plutonium. *N,N*-dialkylamides are being studied in France (Acher et al., 2017; Condamines and Musikas, 1992; Moeyaert et al., 2016), India (Gupta et al., 2000; Pathak et al., 2010; Ruikar et al., 1992, 1993) and in Japan (Ban et al., 2014, 2016) for their ability to extract uranium and plutonium from concentrated nitric acid solutions. Among this family, some branched-alkyl monoamides have the advantage to separate U(VI) and Pu(IV) by decreasing the HNO_3 concentration. Monoamides show also high U/FP selectivity giving the opportunity to reduce the number of extraction cycles to only one and are highly stable toward radiolysis. The mixture of DEHBA (*N,N*-di-2-ethylhexyl-butanamide) and DEHiBA (*N,N*-di-2-ethylhexyl-isobutanamide) was selected in France and successfully hot tested in 2015 at the CEA's Atalante facility in laboratory-scale mixer-settlers (Sorel et al., 2017). The scientific feasibility of the “1 cycle process without redox control” was demonstrated by a quantitative recovery of uranium and plutonium, sufficiently purified from the fission products to reach ASTM specifications (ASTM, 1996, 2015). To respect Generation IV directives, a co-management of uranium and plutonium is planned in the process and a well-known fraction of uranium is co-stripped with Pu in the U/Pu partitioning step (Fig. 6). The U/Pu ratio should be defined by proliferation constraints and MOX fabrication input requirements. The U/Pu ratio in the Pu product was carefully monitored during the 2015 hot test and the value of 0.33 measured at the steady state was consistent with the target.

New asymmetrical *N,N*-dialkylamides are currently under assessment (single molecule, less viscous) and the best candidate will be tested in 2021 on an actual LWR MOX feed (Milanole et al., 2019). In Japan, *N,N*-dialkylamides are also studied for U and Pu separation from MOX fuel solutions and a 2-cycle strategy was chosen to recover U and Pu from MOX fuels: a first separation of the main part of uranium with DEHDMPA and the separation of Pu along with the residual U with DEHBA in a second step. A hot test was recently performed and showed good performances for U and Pu separation (Ban et al., 2014, 2016).

Fig. 6 Simplified flowsheet of an advanced separation process in 1 cycle and redox free for U and Pu separation from MOX fuel solutions.

Fig. 7 A 1-cycle 'Advanced PUREX' process tested in centrifugal contactors with co-recovery of a mixed (U,Np,Pu) product from a simulated MOX feed and using complexant based stripping for plutonium separations.

Complexant based plutonium stripping

The second strategy proposes the retention of the TBP (or similar tri-alkyl phosphate) for co-extraction of uranium and plutonium in the primary extract-scrub step but then separates U from Pu by the complexation of Pu(IV) using an aqueous phase ligand that is selective for tetravalent actinides over the hexavalent uranyl ion. Aceto-hydroxamic acid (AHA) has been demonstrated to be a very effective ligand for achieving this 'complexant based Pu stripping' (Birkett et al., 2005). Advantages of complexant based stripping with AHA include fast kinetics, no requirement for hydrazine and ability to process high Pu content feeds. As AHA is a CHON molecule it can be decomposed to gases rather than adding to waste volumes. The high selectivity of AHA for Pu(IV) over U(VI) is demonstrated by their respective stability constants (at 22 °C; ionic strength = 2 mol/L) (Carrott et al., 2007):

$$\text{Log}_{10}\beta_1 (\text{UO}_2^{2+} - \text{AHA}) = 7.94$$

$$\text{Log}_{10}\beta_1 (\text{Pu}^{4+} - \text{AHA}) = 14.2$$

Since it is a substituted hydroxylamine, AHA is also redox active and can rapidly reduce extractable Np(VI) to inextractable Np(V) which presents the opportunity to route the neptunium with the plutonium stream for burning in fast reactor fuels (Birkett et al., 2007). AHA, however, in acid solution is slowly hydrolyzed to hydroxylamine and acetic acid which means it is best used in short residence time solvent extraction equipment, i.e. centrifugal contactors. Pu(IV) can be slowly reduced to Pu(III) but this is related to the hydrolysis of AHA and is not relevant under normal operating conditions (Carrott et al., 2008). A number of flowsheet tests with AHA have been reported as part of 'advanced PUREX' process development in the United Kingdom, India, USA (the UREX process), France and Russia (Collins, 2018; Herbst et al., 2011). Fig. 7 illustrates an example of one of these tests that produced a mixed (U,Np,Pu) product (with a U/Pu ratio of ~1) and a pure bulk U product from a simulated MOX feed (Taylor and Mathers, 2019). A technetium rejection stage was added to manage the specific problem of technetium decontamination in the PUREX process (Taylor, 2021). Recent work has also confirmed that AHA can be used to produce mixed U + Pu products that are likely to be preferred in future reprocessing.

Application of crystallization for uranium separation

The third strategy considered here is to replace part of the solvent extraction-based reprocessing with an alternative aqueous separation technology e.g. ion exchange or extraction chromatography. Perhaps the most promising option of this type that can be applied to high Pu content FR fuel reprocessing is the use of crystallization as proposed in the New Extraction System for TRU recovery or NEXT process that has been developed by JAEA (Japan) for recycling of spent FR fuels (Collins, 2018; Minato, 2015; Nakahara et al., 2007; Yano et al., 2007). Following dissolution, the liquor is cooled to separate a large amount (>70%) of the uranium as uranyl nitrate hexahydrate (UNH), by crystallization, and to increase the Pu/U ratio. A 1-cycle solvent extraction flow-sheet based on the PUREX process, i.e. using TBP as the extractant, then co-recovers the residual uranium, plutonium and neptunium. (The minor actinides, americium and curium, can be recovered by an extraction chromatography step on the aqueous raffinate). Some precautions must be taken to ensure Pu is present as Pu(IV) (since Pu(VI) will co-crystallize with the uranium) and to minimize contamination due to $\text{Cs}_2\text{Pu}(\text{NO}_3)_6$. The U and Pu (and Np) can then be co-extracted away from the fission products in the first stage of the solvent extraction flowsheet and then co-backwashed with careful control of temperature and nitric acid concentration, avoiding conditions that lead to plutonium (IV) hydrolysis reactions. The NEXT process has been tested with FR MOX fuel from the Joyo reactor in centrifugal contactors at the lab scale in the CPF Facility at JAEA.

Adaptation of processes for Pu conversion and FR MOX fabrication

At the end of the partitioning process, the solution of plutonium and uranium nitrates has to be converted into a mixed oxide (U,Pu) O_2 . The addition of uranium and the increase of Pu quantities in the cycle require the adaptation of the conversion step to higher metal flows. The capacity of the conversion process should be increased by approximately one order of magnitude compared to the industrial capacity of the current industrial Pu conversion workshop. To avoid a multiplication of the precipitation lines in a future plant, a compact and high-capacity process has to be designed for the quantitative (U + Pu) co-solidification and their calcination into a mixed oxide. As redox-free processes are mostly encouraged, an innovative co-conversion process of U(VI) and Pu(IV) was proposed. A denitration route based on an advanced thermal denitration of U(VI) and Pu(IV) solution in the presence of organic additives (ADAO process, see Fig. 8) shows promising results and has been selected as the CEA reference route for co-conversion (Leblanc et al., 2019). 15 g of $\text{U}_{0.8}\text{Pu}_{0.2}\text{O}_{2.2}$ were recently synthesized with this technique. The powder was found to be compatible with the pelletizing process after production of dense and homogenous MOX pellets. Direct premixing of Pu and U in solution instead of co-milling PuO_2 and UO_2 powders offers a better homogeneity in the final pellet and limits dust dissemination.

FR MOX fabrication is usually done by classical metallurgical powder processes (Marin, 2021). As depicted in Fig. 9 (left side), depleted UO_2 , PuO_2 and recycled powders (scraps) are first intimately mixed by ball milling. Then, after a granulation step, pellets are obtained by pressing and sintering. More than 100 t of FR MOX fuels were produced at the ATPu in Cadarache using this co-milling process from 1963 to 1999 to feed Phenix and SuperPhenix reactors. Based on this industrial feedback, the fabrication process was recently optimized. In addition to an improved automation and flexibility, this Advanced SFR process was simplified to lower the dust build-up to reduce the workers exposure (suppression of ball milling and scraps crushing milling steps). The process was also adapted in order to accept a mixed (U,Pu) O_2 obtained by oxalic co-precipitation as an input of the fabrication scheme (Vaudez et al., 2013).

To go further and suppress any powder handling in the first steps, innovative fabrication processes such as “wet routes” are under development. The most promising route consists of a freeze granulation of a UO_2/PuO_2 suspension followed by water elimination by lyophilisation (La Lumia et al., 2019) (Fig. 10). The small and homogeneous granules obtained are then pressed to give dense pellets after dedicated sintering. MOX pellets containing 15% of Pu have been recently obtained from this method. Microstructural analysis shows a high U/Pu homogeneity and a high density after sintering (>99% of Theoretical Density was achieved).

Fig. 8 Description of the advanced thermal denitration of U(VI) and Pu(IV) solution in presence of organic additives (ADAO process).

Fig. 9 Comparison between the advanced SFR MOX fuel fabrication process and the co-milling process used for Phenix and SuperPhenix fuel production.

Fig. 10 Schematic principle of the MOX fabrication process by freeze granulation.

The impact of FNR-Pu to waste characteristics and conditioning processes

Characteristics of used FR MOX fuels (summarized in Fig. 1) will impact waste management, and thus strongly influence the technical solutions needed to be implemented for the treatment of the wastes arising from the future generation reprocessing plants. First, the higher quantity of stainless steel pieces in FR MOX subassemblies will increase the amount of intermediate-level waste produced between LWR UOX/MOX and FR MOX spent fuel reprocessing. Then, metallic fission products such as platinum group metals (Ru, Rh, Pd, Mo, etc.) will be more concentrated in the solid residues recovered after dissolution and clarification. These elements being responsible for partial sedimentation in the glass matrices, their incorporation in the glass could involve difficulties at the vitrification step (Bart, 2021). Finally, the higher Pu content will require a much better recovery of Pu from the cladding and the solid residues, in order to limit the losses of Pu in the ultimate wastes (which will go to the deep geological repository) to approximately the same value as obtained from current reprocessing of UOX fuels. To tackle these issues, a melting process has been proposed for the simultaneous conditioning of stainless steel cladding and solid residues (Ladirat et al., 2018) (Fig. 11). Melting allows a better homogeneity and higher density of the metallic waste compared to the compacting process currently used in the reprocessing of LWR fuels. Then, solid residues (containing a large part of metallic elements) could be incorporated with the cladding in the melting process, avoiding any vitrification issues. Eventually, residual plutonium oxide still contained in the fuel cladding and in the solid residues could be recovered by the addition of a specific slag in the melting process.

Laboratory-scale experiments on synthetic FR representative waste (stainless steel with metallic FP residues and Hf and Ce used as U, Pu surrogates) have recently confirmed the good incorporation of solid residues in the melt and the selective recovery of cerium oxide in the slag. Up to 3 wt% of metallic elements (Ru, Mo, Pd) were quantitatively incorporated into the molten metal without any issues. A SAC-type slag (based on Silica, Aluminum oxide, and Calcium oxide) at 1–5 wt% was required to recover the oxides released by the melt (Hf, Ce in particular) (Ladirat et al., 2018).

Increased quantities of fission products and minor actinides (by a factor 3 compared to UOX fuels) as well as the higher contents of iron, nickel and chromium (caused by partial corrosion of stainless steel cladding) require the development of new glass matrices

Fig. 11 Example of an optimized flowsheet for FR MOX waste management.

to reduce the number of waste canisters ultimately produced. Among the borosilicate glasses, the peraluminous-type formulations (Piovesan et al., 2017; Gasnier et al., 2014) seem to be of considerable interest to incorporate higher quantities of fission products and to increase the solubility of Cr, Fe in the glass matrix. Incorporation of higher concentrations of Cr and Fe in the glass was indeed pointed out as an issue for FR MOX treatment. Elsewhere, alternative processes to vitrification such as immobilization in ceramic matrices are also under development (Chen et al., 2016; Maddrell, 2013; Vance et al., 2016).

Conclusion

The specificities of FR fuels compared to LWR fuels and the increase of Pu content in the fuel require adaptation of the existing processes to successfully multi-recycle plutonium in future closed fuel cycles. Based on the global experience already acquired on LWR and FR fuels recycling, and on new innovative developments arising from new R&D programs, technical solutions are being proposed for each of the main steps of the future generation treatment/recycling plant. Some of the main innovations that are under investigation in global R&D programs, and that have been introduced in this chapter, are listed below:

- Oxide/cladding separation to optimize head-end operations, improve the dissolver compactness and speed up dissolution kinetics;
- “1-cycle process without redox” for uranium and plutonium separation by solvent extraction with N,N-dialkylamides molecules;
- U(VI) and Pu(IV) conversion into mixed oxides without redox control by direct denitration with organic additives;
- MOX fuel fabrication using “wet routes” avoiding powder milling;
- Melting process for the conditioning of fuel cladding pieces and solid residues in addition with a dedicated slag for Pu recovery and decontamination.

Building on past industrial scale experience of reprocessing MOX fuels, promising results have been obtained on these different steps in France and experiments are in progress to validate the technical option selected for each step. Based on these results, a general system analysis will be made by an integration of the different processes in a future plant in order to check the links between the different steps, to confirm the benefits of each options and to be sure that all the selected options can be integrated together in the same flowsheet.

Similar studies, to a greater or lesser extent, are occurring in India, China, Russia, Japan, the United Kingdom and elsewhere; including multi-national efforts sponsored by EURATOM European Union framework programs; the OECD-NEA and IAEA. These global efforts are building confidence that the FR fuel recycling needed to take full advantage of the benefits presented by Generation IV fast reactors and the fully closed fuel cycle can be realized later this century.

Glossary

Cyanobacterium Any of a major group (Cyanobacteria) of photosynthetic bacteria that produce molecular oxygen and use water as an electron-donating substrate in photosynthesis.

Decontamination factor (acronym DF) Ratio of the initial amount of activity in a stream to the final amount of activity in a stream following the treatment by a given process.

Electro deionization A water treatment technology that utilizes electricity, ion exchange membranes and resin to deionize water and separate dissolved ions (impurities) from water. It differs from other water purification technologies in that it is done without the use of chemical treatments and is usually a polishing treatment to reverse osmosis.

Electrodialysis A combination of electrolysis and dialytic diffusion in which an applied electric potential difference across an ion-exchange membrane drives salt ions from the solution on one side of the membrane to the solution on the other side. This process is usually carried out in a stack, in which alternating anion and cation exchange membranes are placed between two electrodes. Applying a current to this stack will produce alternating streams of permeate and concentrate.

Flocculent A substance added to a suspension to enhance aggregation of the suspended particles in the form of flocs. In the case of Actiflo™-Rad, the flocs are fixed on micro-sand to enhance the sedimentation.

Geopolymer An alternative cementitious material synthesized by combining source materials that are rich in silica and alumina with strong alkali solutions such as potassium or sodium hydroxide.

Heterogeneous photo catalysis Photocatalysis is the acceleration of a photoreaction in the presence of a catalyst. In catalyzed photolysis, light is absorbed by an adsorbed substrate. In photogenerated catalysis, the photocatalytic activity depends on the ability of the catalyst to create electron-hole pairs, which generate free radicals (e.g., hydroxyl radicals: $\bullet\text{OH}$) able to undergo secondary reactions. Heterogeneous catalysis has the catalyst in a different phase from the reactants. Most common heterogeneous photocatalysts are transition metal oxides and semiconductors.

Highly active waste Waste for which management is a priority due to its very high levels of radioactivity above 370 GBq/kg.

Ion exchanger Polyelectrolyte (essentially as granular or bead forms suitable for packed bed) which has ions weakly attached to it; typically used is HOH type resin. When a liquid is passed across this bead, it will readily exchange the ions on the bead with ions of the same charge in the liquid. There are two types of resins, cation and anion resins. The cation resin has a positive ion attached in the hydrogen (the H part of HOH resin) form. The anion resin has a negative ion attached in the hydroxide (the OH part of HOH resin) form.

Low and intermediate level waste Comes from objects that are contaminated by contact with radioactive products but that are not radioactive in themselves. The radioactivity must be below 370 GBq/t (10 curies) for beta emitters and 3.7 GBq t^{-1} for alpha emitters (one hundredth).

MetalHexaCyanoFerrates (acronym MHCF) MHCF is a porous coordination polymer, consisting of metal cations M^{a+} and hexacyanoferrate anions $[\text{Fe}(\text{CN})_6]^{b-}$. A historical pigment, Prussian Blue (PB), $\text{Fe}_4[\text{Fe}(\text{CN})_6]_3$, is one of the MHCs. MHCF

has a porous network in its crystal constituted by two types of pores. One is the interstitial sites surrounded by a cubic cage consisting of eight metals bridged by 12 cyano-groups (CN). The other includes vacancy sites implemented by the introduction of $[\text{Fe}(\text{CN})_6]$ vacancies.

Photo-Fenton reaction Photochemical degradation method for organic contaminants using hydrogen peroxide and ferrous iron as a catalyst.

Reverse osmosis (acronym RO) The most exploited membrane operation. In reverse osmosis the feed water is pressurized (to about two to three times its osmotic pressure in order to overcome friction losses and to maintain an adequate flow rate) and forced through the membrane. Relatively pure water permeates through the membrane while a concentrated solution leaves as reject.

Introduction

A general principle applied in radiological protection and waste management is a preference for options that focus on “concentration and containment” of radioactivity over “dilute and disperse.” Thus liquid effluent decontamination consists—most of the time—in transferring radioactive contaminants more or less diluted in an aqueous stream into a solid concentrated waste. However, it is mandatory to first evaluate the safety of the decontamination process as well as of the disposal of the ultimate waste with regards to potential increase in operator doses and accidental discharges. When its activity (in Bq l^{-1}) is below the authorized limit, the clean effluent may be discharged to the environment possibly after a suitable decay period in tanks (IAEA-TECDOC-1638, 2010). The solid waste is generally immobilized in a stable matrix such as cement or even in glass for long-term storage or disposal.

Following that principle the decontamination of liquid effluents is based on a combination of abatement techniques which constitute the so called Best Available Techniques (OECD, 2003; IAEA-TECDOC-1336, 2003). The application of these BAT depend on the nature of the radioactive effluent (temperature, pH, salinity, presence of organic matter or suspended solids, level of radioactivity) but also on the volume to be treated. BAT are evaluated considering the maturity of the technology, its effectiveness, flexibility, costs, safety, reliability, operability and maintainability, occupational radiation exposure, secondary solid waste production and ease of decommissioning.

Usually the majority of radioactive liquid effluent originate from Nuclear Power Plants (NPP) and Fuel-Cycle Facilities (FCC) but it is worth noting that some are produced by the medical sector (99Tc for example), the research centers and other industrial plants all of them being characterized by a wide variety.

Much work has been done for developing optimized or innovative BAT but some challenges still remain in the management of potentially huge volumes of resulting solid residues (Zhang et al., 2019). Keeping in mind this issue, this article aims at giving an overview on the different abatement techniques used for the decontamination of aqueous effluents. Recent developments are highlighted. A case study based on the management of the huge amount of contaminated water produced after the Fukushima Daiichi NPP accident is presented as an illustration of the challenges faced in an emergency.
